CYCLOPÆDIA

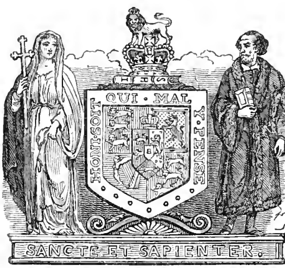
OF

ANATOMY AND PHYSIOLOGY.

EDITED BY

ROBERT B. TODD, M.D. F.R.S.

FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS;
PHYSICIAN TO KING'S COLLEGE HOSPITAL; AND
PROFESSOR OF PHYSIOLOGY AND OF GENERAL AND MORBID ANATOMY IN KING'S COLLEGE,
LONDON, ETC. ETC.



VOL. III.

INS —— PLA.

LONDON:
SHERWOOD, GILBERT, AND PIPER,
PATERNOSTER-ROW.

1847.

CONTRIBUTORS.

ROBERT ADAMS, Esq.
Surgeon to the Richmond Hospital, and Lecturer on Anatomy and Surgery, Dublin.

B. ALCOCK, M.B. Dublin.

W. P. ALISON, M.D. F.R.S.E.
Prof. of the Pract. of Med. in the Univ. of Edin. &c.

JOHN ANDERSON, Esq. M.E.S. Richmond.

J. APJOHN, M.D. M.R.I.A.
Prof. of Chem. to the Royal Coll. of Surgeons, Ireland.

VICTOR AUDOUIN, M.D. Paris.
Professeur-Administrateur au Musee d'Histoire Naturelle.

B. G. BABINGTON, M.D. F.R.S.
Physician to Guy's Hospital.

THOMAS BELL, F.R.S.
Professor of Zoology in King's College, London.

CHARLES BENSON, M.D. M R.I.A.
Prof. of Med. to the Royal Col. of Surgeons, Ireland.

J. BISHOP, F.R.S. London.

JOHN BOSTOCK, M.D. V.P.R.S. London.

W. BOWMAN, F.R.S.
Assistant-Surgeon to the King's College Hospital and the Royal Ophthalmic Hospital, Moorfields, and Demonstrator of Anatomy, King's College, London.

J. E. BOWMAN, Esq.
Demonstrator of Chemistry in King's College, London.

W. T. BRANDE, F.R.S.
Professor of Chemistry to the Royal Institution, &c.

J. E. BRENAN, M.D.

G. BRESCHET, M.D.
Surgeon to the Hotel-Dieu, Paris.

W. BRINTON, Esq.
Demonstrator of Anatomy in King's College, London.

W. B. CARPENTER, M.D. F.R.S.
Lect. on Physiology at the London Hospital, &c.

JOHN COLDSTREAM, M.D. Leith.
Memb. of the Wernerian Nat. Hist. Soc. of Edinb. &c.

DAVID CRAIGIE, M.D. F.R.S.E.
Fellow of the Royal College of Physicians, Edinburgh, &c.

T. BLIZARD CURLING, Esq.
Lect. on Surg. and Assist. Surg. to the Lond. Hospital.

G. P. DESHAYES, M.D. Paris.

A. T. S. DODD, Esq.

H. DUTROCHET, M.D.

W. F. EDWARDS, M.D. F.R.S.

H. MILNE EDWARDS, M.D.
Prof. of Nat. History to the College of Henry IV., and to the Central School of Arts and Manufactures, Paris.

ARTHUR FARRE, M.D. F.R.S.
Professor of Midwifery in King's College and Physician Accoucheur to King's College Hospital.

R. D. GRAINGER, F.R.S.
Lect. on Anat. and Phys. at St. Thomas's Hospital.

R. E. GRANT, M.D. F.R.S. L. & E.
Fell. of the Roy. Coll. of Physicians, Edinb. and Prof. of Comp. Anatomy and Zoology in Univ. College, &c. &c.

W. A. GUY, M.D.
Prof. For. Med. King's College, London, and Physician to King's College Hospital.

M. HALL, M.D. F.R.S. L. & E. London.

HENRY HANCOCK, Esq.
Lect. on Anat. and Physiology at, and Surgeon to the Charing-Cross Hospital.

ROBERT HARRISON, M.D. M.R.I.A.
Prof. of Anat. and Surg. in the Univ. of Dublin.

JOHN HART, M.D. M.R.I.A.
Prof. of Anat. in the Royal Coll. of Surg. Dublin.

A. HIGGINSON, Esq. Liverpool.

ARTHUR JACOB, M.D. M.R.I.A.
Professor of Anatomy and Physiology to the Royal College of Surgeons in Ireland.

GEORGE JOHNSON, M.D.
Assistant Physician to King's College Hospital, and resident Medical Tutor in King's College, London.

T. RYMER JONES, F.R.S.
Prof. of Comp. Anat., in King's College, London.

T. WHARTON JONES, F.R.S. London.

T. WILKINSON KING, Esq.

SAMUEL LANE, Esq.
Lecturer on Anatomy, St. George's Hospital, London.

F. T. MACDOUGALL, Esq.

JOHN MALYN, Esq.

C. MATTEUCCI.
Professor of Physics in the University of Pisa.

ROBERT MAYNE, M.D.
Lect. on Anat. & Phys. Richmond Hospital, Dublin.

W. A. MILLER, M.D. F.R.S.
Professor of Chemistry in King's College, London.

W. F. MONTGOMERY, M.D. M.R.I.A.
Fellow of and Professor of Midwifery to the King and Queen's College of Physicians in Ireland.

GEORGE NEWPORT, F.R.S.
Vice-Pres. of the Entomological Society of London.

R. OWEN, F.R.S. F.G.S.
Hunterian Professor of Comparative Anatomy and Physiology to the Royal College of Surgeons in London.

JAMES PAGET, Esq.
Lect. on Anat. & Phys. St. Bartholomew's Hospital.

RICHARD PARTRIDGE, F.R.S.
Prof. of Descrip. and Surg. Anat. in King's Coll. Lond.

BENJAMIN PHILLIPS, F.R.S. London.
Surgeon to the Westminster Hospital.

SIMON ROOD PITTARD, Esq. London.

W. H. PORTER, Esq.
Prof. of Surgery to the Royal Coll. of Surg. in Ireland.

J. C. PRICHARD, M.D. F.R.S.
Corresponding Member of the Institute of France, Member of the Royal Academy of Medicine of Paris.

G. O. REES, M.D. F.R.S.
Assistant Physician to Guy's Hospital.

J. REID, M.D.
Prof. of Medicine in the University of St. Andrews.

EDWARD RIGBY, M.D. F.L.S.
Lect. on Midwifery at St. Bartholomew's Hospital.

J. FORBES ROYLE, M.D. F.R.S. F.G.S.
Professor of Materia Medica in King's College, London.

HENRY SEARLE, Esq. London.

W. SHARPEY, M.D. F.R.S.
Prof. of Anat. and Physiol. in Univ. Coll. London.

JOHN SIMON, F.R.S.
Lecturer on Pathology, St. Thomas's Hospital.

J. Y. SIMPSON, M.D.
Fellow of the Royal College of Physicians, and Professor of Midwifery in the University of Edinburgh.

SAMUEL SOLLY, F.R.S.
Assistant Surgeon to St. Thomas's Hospital.

GABRIEL STOKES, M.D.

J. A. SYMONDS, M.D.
Physician to the Bristol General Hospital, and Lecturer on the Theory and Practice of Medicine at the Bristol Medical School.

ALLEN THOMSON, M.D.
Fellow of the Royal College of Surgeons, and Professor of the Institutes of Medicine in the University of Edinburgh.

JOHN TOMES, Esq.
Surgeon-Dentist to the Middlesex Hospital.

WM. TREW, Esq.

W. VROLIK,
Prof. Anat. and Phys. at the Athenæum of Amsterdam.

RUDOLPH WAGNER, M.D.
Prof. of Med. & of Comp. Anat. in the Roy. Uni. Erlangen.

W. H. WALSHE, M.D.
Physician to University College Hospital.

R. WILLIS, M.D.

W. J. ERASMUS WILSON, F.R.S.
Consulting Surgeon to the St. Pancras Infirmary.

may be inferred, with perfect confidence, to take place throughout the whole range of the animal kingdom, and even that some of them must be performed with greater energy and precision in some of the lower tribes than in man. The different external senses attain their highest perfection in different animals; that of smell, for example, probably in the predaceous mammalia, that of touch in the antennæ of insects, and that of sight in the predaceous birds; it is not likely that any one is enjoyed in its highest perfection by man; and what have been accurately distinguished from mere the *emotions* of fear, of joy, of affection, of anger, even of jealousy, are as distinctly indicated by their actions as by those of man; that under the influence of these emotions their mental operations are excited or depressed, and their attention fixed or distracted, and their volition excited, as in our own case; and that their actions are habitually guided by a clear perception, or rather, we should say, by continual correct applications, of a first principle of belief, which is generally admitted to be an ultimate fact in the constitution of the human mind, and on which much stress has been

THE

CYCLOPÆDIA

OF

ANATOMY AND PHYSIOLOGY.

INSTINCT.—This word is often applied to the mental acts of the lower animals, as if it were truly applicable to the whole of these acts; but a little consideration will shew, *first*, that this word, in its more approved and correct acceptation, is applicable only to a *part* of the mental operations, which may be inferred from the observation of the actions and habits of animals; and *secondly*, that in this restricted sense, the term is applicable to a part of the operations of the human mind itself; and that the subject of instinct cannot be thoroughly understood, unless information regarding it is sought in the consciousness of our own minds, as well as in the observation of other living beings. The study of this subject is therefore equally important as a part of natural history, of mental philosophy, and of human physiology; and is a good illustration of the necessity of this latter science being based on the observation and generalization of the laws and conditions of vital action throughout the whole extent of the animal creation.

It is obvious, indeed, that various mental acts, of which we are conscious in ourselves, may be inferred, with perfect confidence, to take place throughout the whole range of the animal kingdom, and even that some of them must be performed with greater energy and precision in some of the lower tribes than in man. The different external senses attain their highest perfection in different animals; that of smell, for example, probably in the predaceous mammalia, that of touch in the antennæ of insects, and that of sight in the predaceous birds; it is not likely that any one is enjoyed in its highest perfection by man; and what have been accurately distinguished from mere sensations as the *perceptions* of external things, i. e. the notions as to the qualities of these, which naturally present themselves to our minds in consequence of sensations being felt, would seem in various instances to follow the sensations more quickly and more surely in other animals than in us; for it is generally allowed that what appear to be *acquired* perceptions of the eye to us, i. e. the notions of the distance, size, and form of visible objects, are instantaneously made known to many of the lower animals the very first time that those objects make impressions on their retinæ; the faculty of *Intuition*, which we must admit as part of the source of our own knowledge, appears to exist in greater perfection in other animals, and the notions of external things which they thus acquire are amply sufficient to regulate their muscular motions.

It is equally plain that many of the strictly mental acts, of which our complex trains of thought are composed, are habitually performed by animals; that they have a perfect *recollection* of past sensations, implying the exercise of the powers of memory and of conception; that the *emotions* of fear, of joy, of affection, of anger, even of jealousy, are as distinctly indicated by their actions as by those of man; that under the influence of these emotions their mental operations are excited or depressed, and their attention fixed or distracted, and their volition excited, as in our own case; and that their actions are habitually guided by a clear perception, or rather, we should say, by continual correct applications, of a first principle of belief, which is generally admitted to be an ultimate fact in the constitution of the human mind, and on which much stress has been tions, the sensations, the voluntary powers, the memory and instinct of the animals are all brought into play; but we have no reason to believe that the animals performing them are capable of anticipating their ultimate result.

In all cases, those actions which are entitled to the appellation of Instinctive are generally understood to be characterized by two marks, quite sufficient to distinguish them from the effects of voluntary power guided by reason: 1. That, although in many cases experience is required to give the will command over the muscles concerned in them, yet the will, when under the influence of the instinctive determination, acts equally well the first time as the last; no experience or education is required, in order that the different voluntary efforts requisite for these actions may follow one another with unerring precision; and 2. That they are always performed by the same species of animal nearly, if not exactly, in the same manner; presenting no such variation of the means applied to the object in view, and admitting of no such improvements in the progress of life or in the succession of ages, as we observe in the habits of individual men, or in the manners and customs of nations, adapted to the attainment of any particular ends by those voluntary efforts which are guided by Reason. "The manufactures of animals," says Dr. Reid, "differ from those of men in many striking particulars. No animal of the species can claim the invention. No animal ever introduced any new improvement, or variation from the former practice. Every one has equal skill from the beginning, without teaching, without experience or habits. Every one has its art by a kind of inspiration, i. e. the ability and inclination of working in it without any knowledge of its principles." A third distinctive mark, naturally resulting from the last, is at least equally characteristic, although much less generally observable,—that these instinctive actions are seen to be performed in circumstances which reason informs us to be such as to render them nugatory for the ends which are usually accomplished by them, and for which they are obviously designed. The efforts made by migratory birds, even when confined, at their usual period of migration,—the mistake of the flesh-fly who deposits her eggs on the carrion-plant instead of a piece of meat,* or of the hen who sits on a pebble instead of an egg, or of the mule which remains immoveably fixed by terror instead of escaping from the flood which threatens to overwhelm it, (as exemplified in the inundation of the valley of Luisnes in Savoy in 1818,) or of the bee which gathers and stores up honey even in a climate where there is no winter,† are so many proofs, that an instinctive action is prompted by an impulse, which results merely from a particular sensation or emotion being felt, not by anticipation of the effect which the action will produce.

* Kirby.

† See Kirby and Spence, Introduction to Entomology, vol. ii. p. 469.

But, in order to have demonstrative proof of the essential difference between instinct and reason, and of the correctness of the view which we take of the nature of that mental impulse which prompts what we call the instinctive actions of animals, it is only necessary to reflect on what passes within ourselves on occasion of certain actions of the very same class being performed by us. It is difficult, indeed, in adult age, to distinguish those actions which we perform instinctively from those which we have learnt by repeated efforts to perform habitually; but in the case of infants we see complex actions, useful or necessary to the system, performed with perfect precision at a time when we are certain that the human intellect is quite incompetent to comprehend their importance or anticipate their effects; yet we cannot doubt that it is by a mental impulse that they are excited, because we perform the same actions in the same circumstances in adult age, and are then conscious of the impulse which prompts them. "It is an instinct," says Bichat, "which I do not understand, and of which I cannot give the smallest account, which makes the infant, at the moment of birth, draw together its lips to commence the action of sucking," to be followed by the still more complex act of deglutition. "This cannot be ascribed to the mere novelty of the sensations which it experiences from external objects, for the general effect of such sensations is to determine various agitations or irregular movements indeed, but not an uniform movement, directed to a determinate end. If we examine different animals at the moment of birth, we shall see that the special instinct of each directs the execution of peculiar movements. Young quadrupeds seek the mammæ of their mothers, birds of the order Gallinaceæ seize immediately the grain which is their appropriate nourishment, while the young of the Carnivorous birds merely open their mouths to receive the food which their parents bring to their nests. In general, it is very important to distinguish the irregular or varied movements which, at the moment of birth, are produced simply by the new sensations and excitements which the body receives, from those definite actions which are the effect of instinct, a cause of which we can give no further explanation."

In fact, when we attend to the simple action of deglutition,* as performed in our mature years, we may be conscious that it results from the same instinctive impulse which guided it with unerring precision in the new-born infant, long before the voluntary power of simply raising the hand to the mouth had been acquired. If we were to consult only the gratification of our sensations, we should keep any grateful food in the mouth; for when it is swallowed the gratification immediately resulting from it is at an end, and there is no peculiar pleasure attached, in other circumstances, to the mere act of deglutition; but all we can

* [I. e. that part of the act which is dependent on the voluntary movement of the tongue to pass on the food to the isthmus faucium.—Ed.]

observe by attention to our own feelings on such occasions is, that while we feel the sensations of hunger and thirst, we feel also a propensity, all but irresistible, to swallow whatever grateful food or drink is in the mouth. This propensity is not only prior to reason, but stronger than reason, and prompts us to action more surely and more energetically than the mere recollection of the effects previously resulting from food or drink taken into the stomach could have done.

If we reflect further, we shall find that there are various other sensations, with which we can feel, in our own persons, that an instinctive impulse is naturally linked. The term Appetite does not express the whole of these, although it is only by referring to the action which it uniformly prompts that an appetite can be distinguished from another sensation. Sympathetic movements, such as breathing, coughing, sneezing, vomiting, &c. are ascribed by Whytt and others to sensations; and laughter, weeping, the expression of feeling in the countenance and features, &c. are strictly referable to emotions of mind, and in the performance of all these actions, a propensity which may be called strictly instinctive, because prior to experience, and independent of reasoning, may be frequently and distinctly felt, and is from the first equally effectual in exciting very complex muscular movements, as the impulse to swallow food in the mouth. We may specify several other kinds or modes of action, which we are all conscious of frequently performing, and which we perform on many occasions in obedience, not to any effort of reason, but to a truly instinctive impulse, naturally consequent on certain sensations or emotions, and felt even in adult age to be independent of, as they are in the infant prior to, any anticipation of remote consequences,—viz. 1. those which are prompted by the instinct of self-preservation, (as the winking of the eyelids when the eyes are threatened with injury, the shrinking of any limb or part of the body which is struck, the projection of the arms when we are about to fall forwards on the face,* the act of crying from pain or from fear); 2. those which are prompted by the instinct of shame, as when the saliva escapes from the mouth, when the sphincters fail in their office, or the sense of modesty is outraged; 3. those which are prompted by the instinct of imitation, existing more or less in the early stage of all human existence, and whereby we are all led to fashion our language, manners, and habits, on the model of those around us, and particularly of those persons with whom we have either the most frequent intercourse, or the intercourse which is most fitted to make an impression on our minds; 4. those which are prompted by the emotions of affection and pity, or still more decidedly by the impulse of maternal love, on witnessing the helpless condition of young infants.* We do not enter into details on these subjects at present, but merely mention them as examples, in which we may safely and legitimately avail ourselves of the evidence of consciousness to assure ourselves of the essential peculiarity, and of the paramount authority, of the *instinctive impulse*, as distinguished from the *voluntary effort*, which results from a train of reasoning.

It has been often said that the nature of instinct is absolutely mysterious and inscrutable; but if what has now been stated be correct, this can be said of instinct only in the same sense in which it may be said of all mental acts without exception; the essence of mind, like that of matter, being wholly inscrutable. The *characters* of the instinctive impulse may be distinguished as clearly as those of any other mental act, in the only way in which any such act can be distinguished, viz. by attention to our own consciousness: although we never could have anticipated *à priori* that this kind of mental impulse could have extended to so long continued and complex actions, and to the concerted operations of so many individuals, as the operations of some animals indicate.

Having satisfied ourselves of the existence of certain instinctive impulses, both in the lower animals and in ourselves, essentially distinct from those voluntary efforts which are guided by reason, we need not be perplexed at finding that there is much difficulty in some individual instances, in determining to which class of mental acts particular actions ought to be referred. However difficult it may be in any individual instance, to decide whether an action, of man or of animals, is the effect of a blind instinct, or of reason, anticipating and desiring its consequences, there can be no doubt or difficulty as to the fact, that these two distinct kinds of mental determination to the performance of actions exist.

Neither do we consider it of any importance to enter on the metaphysical speculations which ingenious men have hazarded at different times as to the nature of the agent, by which the instinctive actions may be supposed to be immediately excited. Some philosophers have been so strongly impressed with the admirable adaptation of means to ends which these phenomena present, in animals manifestly devoid of reason, that they have believed them to be in all cases the immediate offspring of the divine intelligence, and have expressed their theory in the form of an axiom, "Deus anima brutorum," which, it is humbly conceived, is admissible only in the same sense in which we assent to the more general assertion, "Deus anima mundi."

Mr. Kirby, in his very learned and elaborate Bridgewater Treatise on the History, Habits, and Instincts of Animals, seems to favour the

* Let any one try the experiment of attempting to fall forward on his face, with his arms extended at his sides, and he will be immediately conscious of the instinctive impulse which urges him to throw forward his arms; and which he feels distinctly and resists with difficulty, even when he knows that he is about to fall only on soft matter which cannot injure him.

[* The greater number of the actions enumerated may, however, be accounted for on the principle of reflux nervous action, now so generally admitted by physiologists.—Ed.]

idea which other philosophers have maintained, of *intermediate agents* between the Divine will and the living beings on earth, by which the actions of the latter are guided;* but in prosecuting this idea he is disposed to regard the proximate cause of instinct, as he expresses it, not as metaphysical, but merely as physical, and to suppose that "light, heat, and air, or any modification of them" may be the intermediate agents "employed by the Deity to excite and direct animals, when their intellect cannot, in their instinctive operations;" and that "the organization of the brain and nervous system may be so varied and formed by the Creator as to respond in the way that he wills, to pulses upon them from the physical powers of nature."†

On this it may be observed that this last sentence expresses no more than the truth, whatever opinion we may form as to the mode, in which the response of the nervous system of an animal to the impressions made on it by physical agents takes place; but if it be meant by the expression, that the proximate cause of instinct is probably not metaphysical but physical, to exclude all mental operation, and all consciousness of effort, from the instinctive actions of animals, we can regard the theory only as a denial of all mental acts or affections in any of the lower animals, and as easily contradicted by the whole analogies of their structure, by observation of their habits, and by the evidence of our own consciousness in the performance of those precisely similar instinctive actions which have been noticed above.

It seems quite unreasonable to doubt that the immediate cause of all the actions that we call instinctive, is a strictly *mental effort*, but the occurrence of that effort in every case when it is required must in all probability be always held as an *ultimate fact* in the animal œconomy; and all speculations as to its intimate nature or proximate cause may be regarded as mere conjectures, on a subject which is beyond the reach of the human faculties. Nor would any thing be gained, in the inference as to final causes, from establishing any one of these conjectures; for the mental constitution of man himself, and of the whole lower animals, is equally a part of the contrivance of the Divine Artificer of the world, as the laws of motion or the properties of light. He who could make man after his own image could assuredly impart such mental propensities to other beings, as well as to man, as were necessary for the ends for which the creation was designed. And when we attempt, in all humility, but at the same time in confident reliance on the mental powers which He has vouchsafed to us, to draw inferences as to His existence and attributes from the study of created things, we do so, not by vainly attempting to comprehend the *nature* of the energy by which any of the changes (physical or mental) occurring around us are effected, but simply by observing the *adaptation of means to ends* in those regular and uniform laws which we are enabled to infer from the observation of such changes,—which we ascribe to His authority, and beyond which we feel that it is not yet given us, by any exercise of our minds, to ascend. In enabling us to draw those inferences, the instincts of animals, as we shall afterwards state, are of peculiar importance; but the inferences are the same, whatever opinion we may adopt as to the mode in which the Divine Intelligence so indicated rules the wills of the animal creation.

Having said so much of the characteristics of this class of phenomena, and endeavoured to set them in the proper point of view, we shall next offer a very rapid sketch of the varied instincts exhibited in the different tribes of animals, arranging them simply according to the purposes which they seem destined to serve, and shall conclude with a few general reflections.

It may be premised that it certainly seems reasonable *à priori* to suppose, that the structure of the nervous system, and especially of the brain, of different animals, will bear some relation to the kind of instinctive propensities which they exhibit. In the size of the sensitive and motor *nerves*, and portions of the cerebro-spinal axis whence these originate, particularly the spinal cord, medulla oblongata, and optic lobes (or corpora quadrigemina), in the higher animals, this relation may be distinctly perceived; and it has been further confidently stated by some phrenologists, that strong evidence of certain of their peculiar doctrines may be deduced from observation of the size and form of the brains of animals, as compared with their instincts; but this last speculation certainly cannot be carried further than the vertebrated animals, which form but a small part of the living beings that are continually guided and ruled by the laws of instinct; and even in them no such relation of the size and form of the brain, or of any part of the brain, to the general intelligence of an animal, or to any particular instinct, has been fully ascertained. Indeed, until some such essential difference shall be observed between the habits and instincts of the dolphin, or other cetaceous animals, and the predaceous fishes, as may correspond to the extraordinary difference of the size and structure of their brains, (that of the former being much larger in proportion to the spinal cord than the human brain, and of complex structure, while that of the latter is not larger than the optic lobes or corpora quadrigemina of the same animal, and of very simple structure,) such speculations may be safely distrusted.*

Mr. Kirby has stated that the principal instincts of animals may be referred to three heads; those relating to their food, those relating to their propagation and the care of their offspring, and those relating to their hybernation. But this enumeration is certainly defective, and indeed will hardly include several which

* See vol. ii. p. 243-4.
† Vol. ii. p. 255-6.

* We cannot suppose this difference to be connected with the difference in the mode of respiration of these animals, because we know that the only part of the central masses of the nervous system of either, concerned in that function, is the medulla oblongata.

he has himself accurately described. The following appears a more comprehensive enumeration. Three great classes of instinctive actions may be distinguished; the first designed for the preservation of individuals; the second for the propagation and support of their offspring; and the third for various purposes important either to the race of animals exhibiting them, or to other animals, but not distinctly referable to either of the former heads.

Each of these classes admits of obvious subdivisions.

I. *Of instincts designed for the preservation of the individuals exhibiting them,* we may enumerate the following:—

1. All animals are endowed with instincts prompting them to some means of escaping or repelling injury or violence, but these are exceedingly various, both as to the kind and as to the degree of complexity of the actions which they excite; from the simple retraction of the tentacula of the infusory Vorticella, or of the Medusa, Polype, or Actinia, up to the active and formidable resistance of the elephant or the tiger. The most common instinct of self-preservation excited by the emotion of fear, is that which prompts to flight, an instinct so obviously existing in the human species, that the effort by which it is resisted has in all ages been regarded with respect; and another very common propensity in animals is that which prompts to concealment. This is often combined with flight, as in most of the Carnivorous Mammalia, the Rodentia, the Cetacea, the diving birds, reptiles, insects, &c.; but some of the higher animals, and many of the Mollusca and insects, and others of the lower tribes, remain quite motionless and counterfeit death when under the influence of fear;* and it is remarkable that when the circumstances of the animals render this mode of defence the most effectual, it is that adopted, in preference to flight, even by single species of families, the other members of which shew no such instinct, as in the case of the ptarmigan, which so frequently cowers among the grey lichen, or the snow on the mountain-tops, instead of taking wing like the moor fowl, or in that of the hedge-hog, which on occasion of any imminent danger makes no effort but that of coiling itself into a ball.

In many instances the instinct either of flight or concealment is aided by very various special contrivances, equally instinctive, fitted either to deceive, or to alarm, or injure an assailant. Some even of the Mollusca, and some of the reptiles, as the toad, squirt water on him; many reptiles and some lower animals, as the scorpion, bee, wasp, &c., even some of the gelatinous radiata,† have the power of emitting irritating matter of greater or less intensity; the electrical animals, as the gymnotus and torpedo, use their appointed weapons; the hedge-hog and porcupine oppose their sharp thorns to any one who attempts to molest them; many insects and some reptiles protect themselves by emitting peculiarly fetid effluvia; the cuttle-fish tribe have the remarkable power of emitting an inky fluid which darkens the water and hides them; and on the other hand there is reason to believe that the phosphorescent light which so many marine animals exhibit, may be suddenly augmented on occasion of any threatening of injury, and serve as a means of defence.* (See LUMINOUSNESS.) The means of defence, and the instincts guiding them, in the case, not only of the higher Carnivorous animals, but many of the stronger of the Herbivorous classes, the elephant, the hog, the horse, the buffalo, the deer, &c. require no illustration.

The instinct which prompts many animals to utter cries when injured or threatened, (as well as on other occasions and for other purposes,) deserves notice as a means of protection, particularly on this account, that as it is one of the instincts which most clearly extends to the human race, so we may perceive in man, as well as in some of the lower animals, that its use is not merely to frighten assailants, but especially to procure assistance and protection for the young animal from its parents.

2. The most conspicuous and most remarkably varied of the instincts under this head are those by which the food of different animals is procured. With the exception of the sponges, and some others of the lowest Zoophyta, in which the nourishment is supplied by currents, all animals have organs corresponding to a mouth and stomach, into which aliments are taken by a process of deglutition, implying sensations and instinctive efforts consequent on these; and in the Articulata and Mollusca, the most important central organ of the nervous system seems to be the nervous collar surrounding the œsophagus, which in the vertebrated animals seems to be developed and subdivided into the first, fifth, and part of the eighth pairs of nerves, with the corresponding portions of the cerebro-spinal axis, by which the sensation of hunger is felt, the suitable nourishment discriminated, and the instinctive effort, whether of deglutition only, or of mastication more or less powerful according to the food, is excited.

In some instances subsidiary instincts are also implanted in certain animals, which are essential to their digestion and nutrition. The art of cookery, as universally practised by the human race, may be said to be the result of experience; but this cannot be said of the propensity of many animals to swallow salt, still less of the swallowing of gravel or pebbles by the graminivorous birds, or of the copious draughts of water, sufficient to store the numerous and peculiar cells of their first and second stomachs, which are taken by the camel

* "In this situation, spiders will suffer themselves to be pierced with pins and torn to pieces, without discovering the smallest sign of pain. This simulation of death has been ascribed to a strong convulsion or stupor occasioned by terror; but this solution of the phenomenon is erroneous. If the object of terror is removed, in a few seconds the animal runs off with great rapidity."—*Duncan on Instinct.*

† Kirby, vol. i. p. 198.

* Ibid, vol. i. p. 178.

or llama before they enter on the deserts, and which enable them subsequently to subsist without water for many days.

But the instincts by which animals are enabled to search for and obtain food may be easily supposed to be much more numerous and varied than those by which they merely seize and swallow it, and in fact furnish the conditions by which the varieties of the whole structure of animals are chiefly determined. Probably the greatest number of animals are nourished by the vegetable world in the living or dead state, and are continually guided by sensations, to which instinctive efforts are attached,—i. e. by appetites,—in the selection of food, which may in general be found and seized without much difficulty. But throughout the whole animal kingdom, from the microscopic animalcules up to the largest of the Mammalia, a very great number of carnivorous animals are found, who subsist on, and continually repress the numbers of, the herbivorous tribes; and it may easily be supposed that the instincts implanted in these animals, which oppose and counteract the varying efforts at self-preservation already mentioned, will be more varied, and bear more marks of contrivance and ingenuity. Accordingly, from the numerous Vorticellæ, or other animalcules, of the order Rotatoria, which excite currents in the water around them, and so attract into their stomachs many of the smaller animalcules, up to the lion, the whale, or the eagle, we find an infinite number of contrivances and instinctive propensities, served by organs, by which the predaceous animals, of all the orders, are enabled to prey on the others. The Polype, Echinus, and Actinia, for example, among the Zoophyta, seize their prey, as it is brought to them by the waves, with their numerous tentacula; the Entozoa, and the leech and other of the Annelides, have the faculty and the necessary instinct of attaching themselves to the larger animals in the situations which suit them, as the Cirrhipedes or barnacles do to vegetable substances. The cuttle-fish and other predaceous Mollusca have legs furnished with admirably constructed suckers and powerful jaws, and most of the Crustacea have claws and mandibles, sufficient to enable them to seize and destroy marine animals of very considerable size; and it is unnecessary to enlarge on the powerful means of destruction, or on the instincts guiding their use, which are seen in many genera of each of the classes of vertebrated animals. There is often a peculiar instinct guiding each of the Carnivorous Mammalia to the part of the body of its victim where it can most easily inflict a mortal wound, to the throat in the case of a large animal, to the head in that of a small one, of which the cranium may be pierced. In the greater number of them, however, the instinctive actions by which their prey is obtained are distinguished only by power and violence; and although much contrivance is employed for adapting the different parts of the structure to the habits and destination of the animals, there is little apparent ingenuity in the modes in which the animals perform their office in creation. The attitude and gesture of the cat, the pointer, or the tiger, "slow stealing with crouched shoulders on his prey," is an example of instinctive contrivance preliminary to the act of violence. The aspect and expression of many carnivorous animals,—not only of the Mammalia and birds, but of the shark, the cuttle-fish, the scorpion, the tiger-beetle, &c., are so adapted to the feelings and instincts of the animals on which they feed, as often to deprive them of the power of flight or resistance; and it is maintained by many, that some of the predaceous animals have the power of fascinating their prey by merely fixing their eyes on them. Many have ascribed this power to the serpent; and Mr. Kirby asserts it with confidence of the fox.* A few only of the predaceous animals, as the dog and wolf, have the instinct of associating together for procuring their prey. It has been stated that the pelican and the dog-fish have a similar instinct.†

But the more striking indications of contrivance in the actions prompted by this instinct are to be found in some of the less powerful of the carnivorous tribes. The Lophius Piscatorius or fishing-frog, although a large fish, having no strength or speed, obtains its prey by stratagem, plunging itself in mud, or covering itself with sea-weed: "it lets no part of it be perceived except the extremity of the filaments that fringe its body, which it agitates in different directions, so as to make them appear like worms. The fishes, attracted by this apparent prey, approach and are seized by a single movement of the fishing-frog, and swallowed by his enormous throat, and retained by the innumerable teeth by which it is armed." ‡ A still more singular art is practised by the Chœtodon rostratus, which feeds on flies, and, as Sir Charles Bell states, actually takes aim at them, and shoots them with a drop of water.§ The instinct of the myrmecophaga or ant-eater, which protrudes the tongue to allure flies to settle on it, and then suddenly retracts it to devour them, also deserves notice. A more complex art is practised by the ant-lion, which digs a pitfall in the track usually followed by ants, and conceals itself in the bottom of it, waiting for its prey. But of all contrivances in the animal creation for procuring food, the most complex and artificial are those of the different genera of spiders, equally curious on account of the peculiar organs by which they spin their webs, as of the peculiar and varied instincts by which they are guided in using them.|| For example, "any common black and white spider (Salticus Scenicus), which may always be seen in summer on sunny rails, &c., when it spies a fly at a distance, approaches softly, step by step, and seems to measure his distance from it by the eye; then if he judges that he is within reach, first fixing

* Vol. ii. p. 269.

§ Bridgewater Treatise, p. 200.
|| See Kirby, vol. ii. p. 184 and 286.

a thread to the spot on which he is stationed, by means of his fore feet, which are much larger and longer than the others, he darts on his victim with such rapidity, and so true an aim, that he seldom misses it. He is prevented from falling by the thread just mentioned, which acts as a kind of anchor, and enables him to recover his station."* Again, the kind of spider that has received the name of Geometric, "having laid the foundation of her net, and drawn the skeleton of it, by spinning a number of rays, converging to a centre, next proceeds, setting out from that point, to spin a spiral line of unadhesive web, like that of the rays, which it intersects, and after numerous circumvolutions finishes this at the circumference. This line, in conjunction with the rays, serves as a scaffolding for her to walk over, and also keeps the rays properly stretched. Her next labour is to spin a spiral or labyrinthiform line from the circumference towards the centre, but which stops somewhat short of it; this line is the most important part of the snare. It consists of a fine thread, studded with minute viscid globules, like dew, which by their viscid quality retain the insects which fly into the net. The snare being thus finished, the little geometrician selects a concealed spot in the vicinity, where she constructs a cell, in which she may hide herself and watch for game; of the capture of which she is informed by the vibrations of a line of communication, drawn between her cell and the centre of her snare."†

3. Many animals are guided by instinct to form habitations for themselves, of very various kinds, for protection against injury and against cold, from the simple contrivance of the earth-worm, which closes the orifice of its hole with leaves or straw, up to the elaborate structures of the bee, the ant, or the beaver. Here we observe a singular but easily understood difference between the inhabitants of water and air. The greater number of the more delicate animals that inhabit the sea, chiefly of the Mollusca and Crustacea, are provided by nature with shells, or very firm integuments, evidently for protection against the violence of the waves, in the formation of which instinct has little or no share; but there are some of the Annelides inhabiting water, as the Sabella and Terebella, and the larvæ of some moths, which have a singular instinct enabling them to form habitations sufficient for their own protection, "by collecting grains of sand and fragments of decayed shells, &c. which they agglutinate together by means of a viscid exudation, so as to form a firm defensive covering, like a coat of mail." This may be stated as the intermediate link between the habitations given to the Mollusca and Crustacea by nature, and those which many land animals have organs and instincts enabling them to form for themselves.

"The manœuvres of the terebella are best observed by taking it out of its tube and placing it under water upon sand. It is then seen to unfold all the coils of its body, to extend its tentacula in every direction, often to a length exceeding an inch and a half, and to catch, by their means, small fragments of shells and the larger particles of sand. These it drags towards its head, carrying them behind the scales which project from the anterior and lower part of the head, where they are immediately cemented by the glutinous matter which exudes from that part of the surface. Bending the head alternately from side to side, while it continues to apply the materials of its tube, the terebella has very soon formed a complete collar, which it sedulously employs itself to lengthen at every part of the circumference with an activity and perseverance highly interesting. For the purpose of fixing the different fragments compactly, it presses them into their places with the erected scales, at the same time retracting the body. Hence the fragments, being raised by the scales, are generally fixed by their posterior edges, and thus, overlaying each other, often give the tube an imbricated appearance.

"Having formed a tube of half an inch or an inch in length, the terebella proceeds to burrow; for which purpose it directs its head against the sand, and contracting some of the posterior rings, effects a slight extension of the head, which thus slowly makes its way through the mass before it, availing itself of the materials which it meets with in its course, and so continues to advance till the whole tube is completed. After this has been accomplished, the animal turns itself within the tube, so that its head is next the surface, ready to receive the water which brings it food, and is instrumental in its respiration. In summer the whole task is completed in four or five hours; but in cold weather, when the worm is more sluggish, and the gluten is secreted more scantily, its progress is considerably slower."‡

The habitation formed by the water-spider, which is not exposed to the violence of the sea, shews much greater delicacy of workmanship, as well as greater variety of instinct.

"The insects that frequent the waters," says Kirby, "require, as well as those that inhabit the earth, predaceous animals to keep them within due limits, and the water-spider is one of the most remarkable on whom that office is imposed by the Creator. To this end her instinct instructs her to fabricate a kind of *diving-bell*, for which purpose she usually selects still waters. Her house is an oval cocoon filled with air, and lined with silk, from which threads issue in every direction, and are fastened to the surrounding plants; in this cocoon, which is open below, she watches for her prey, and even appears to pass the winter, when she closes the opening. It is most commonly entirely under water, but its inhabitant has filled it with air for respiration, by which she is enabled to live in it. She conveys the air in the following manner: she usually swims upon her back, when her abdomen is enveloped in a

* Kirby. vol. ii. p. 298.

† Ibid. p. 295. See also Darwin's Zoon. vol. i. p. 253.

‡ Roget's Bridgewater Treatise, vol. i. p. 279.

bubble of air, and appears like a globe of quicksilver; with this she enters her cocoon, and displacing an equal mass of water, again ascends for a second lading, till she has sufficiently filled her house with it, so as to expel all the water. The males construct similar habitations by the same manœuvres. How these little animals can envelope their abdomen with an air-bubble, and retain it till they enter their cells, is still one of Nature's mysteries that have not been explained."

We need say nothing of the habitations formed by solitary animals of the higher tribes, chiefly by burrowing under ground, for their own protection and comfort; but the most curious of such solitary habitations on the earth's surface are also furnished by the tribe of spiders.

"Some species of spiders, M. Audouin remarks, are gifted with a particular talent for building: they hollow out dens; they bore galleries; they elevate vaults; they build, as it were, subterranean bridges; they construct also entrances to their habitations, and adapt doors to them, which want nothing but bolts, for without any exaggeration, they work upon a hinge and are fitted to a frame. The interior of these habitations is not less remarkable for the extreme neatness which reigns there; whatever be the humidity of the soil in which they are constructed, water never penetrates them; the walls are nicely covered with a tapestry of silk, having usually the lustre of satin, and almost always of a dazzling whiteness.

"The habitations of the species in question are found in an argillaceous kind of red earth, in which they bore tubes about three inches in depth and ten lines in width. The walls of these tubes are not left just as they are bored, but are covered with a kind of mortar, sufficiently solid to be easily separated from the mass that surrounds it." "The door that closes the apartment is still more remarkable in its structure. If the well were always open, the spider would sometimes be subject to the intrusion of dangerous guests. Providence has therefore instructed her to fabricate a very secure trap-door which closes the mouth of it. To judge of this door by its outward appearance, it appears to be formed of a mass of earth coarsely worked, and covered internally by a solid web, which would be sufficiently wonderful for an animal that seems to have no special organ for constructing it; but when divided vertically, it is found to be a much more complicated fabric than its outward appearance indicates, it being formed of more than thirty alternate layers of earth and web emboxed, as it were, in each other, like a set of weights for small scales.

"If these layers of web are examined, it will be seen that they all terminate in the hinge, so that the greater the volume of the door the more powerful is the hinge. The frame in which the tube terminates above, and to which the door is adapted, is thick, arising from the number of layers of which it consists, and which seem to correspond with those of the door; hence the formation of the door, the hinge, and the frame, seem to be a simultaneous operation; except that in fabricating the first, the animal has to knead the earth as well as to spin the layers of web. By this admirable arrangement these parts always correspond with each other, and the strength of the hinge and the thickness of the frame will always be proportioned to the weight of the door.

"The interior surface of the cover to the tube is not rough and uneven like its exterior, but perfectly smooth and even like the walls of the tube, being covered with a coating of white silk, but more firm, and resembling parchment, and remarkable for a series of minute orifices placed in the side opposite the hinge, and arranged in a semicircle; there are about thirty of these orifices, the object of which, M. Audouin conjectures, is to enable the animal to hold her door down in any case of emergency against external force, by the insertion of her claws into some of them." *

But the most extraordinary habitations formed by the instincts of animals are those which are the joint result of the labours of communities; and here we observe the same difference as has been already noticed, between the inhabitants of the air and of the ocean. Many of the animals that inhabit the latter are formed by nature, as Mr. Kirby expresses it, (and evidently with a view to the rude shocks to which they are exposed,) "into a body politic, consisting of many individuals, separate and distinct as inhabiting different cells, but still possessing a body in common, and many of them receiving benefit from the systole and diastole of a common organ; thus by a natural union is symbolized what in terrestrial animal communities results from numerous wills uniting to effect a common object. The land, as far as I recollect, exhibits no instance of an aggregate animal, nor the ocean of one which, like the beaver, lemming, bee, wasp, &c. forms associations to build and inhabit a common house." †

And there is a curious family, named Salpa, in which the individuals are attached to each other almost like bees in their cells at birth, and are afterwards separated when they have acquired strength; thus forming the link between the aggregated sea animals (such as Corals, Madrepores, Sertularia, Flustra, &c.) and the associated land animals.

The habitations that are formed by animals of the latter description, although in very different parts of the scale of beings, afford equally curious evidence of skill and contrivance, and of the wills of numerous individuals, bound together by a common instinct, as surely as the materials of which the aggregate animals are composed. Take, for example, the houses of beavers.

"Beavers set about building some time in the month of August: those that erect their habitations in small rivers or creeks in which the water is liable to be drained off, with wonderful sagacity provide against that evil by

* Kirby, vol. ii. p. 287, et seq.

† Kirby, vol. i. p. 222.

forming a dike across the stream, almost straight where the current is weak, but where it is more rapid, curving more or less, with the convex side opposed to the stream. They construct these dikes or dams of the same materials as they do their lodges, viz. of pieces of wood of any kind, of stones, mud, and sand. These causeways oppose a sufficient barrier to the force both of water and ice; and as the willows, poplars, &c. &c. employed in constructing them often strike root in it, it becomes in time a green hedge in which the birds build their nests.

" By means of these erections the water is kept at a sufficient height, for it is absolutely necessary that there should be at least three feet of water above the extremity of the entry into their lodges, without which, in the hard frosts, it would be entirely closed. This entry is not on the land side, because such an opening might let in wild animals, but towards the water.

" They begin to excavate under water at the base of the bank, which they enlarge upwards gradually, and so as to form a declivity, till they reach the surface; and of the earth which comes out of this cavity they form a hillock, with which they mix small pieces of wood and even stones; they give this hillock the form of a dome from four to seven feet high, from ten to twelve long, and from eight to nine wide. As they proceed in heightening, they hollow it out below, so as to form the lodge which is to receive the family. At the anterior part of this dwelling, they form a gentle declivity terminating at the water, so that they enter and go out under water.

" The interior forms only a single chamber resembling an oven. At a little distance is the magazine for provisions. Here they keep in store the roots of the yellow water-lily, and the branches of the black spruce, the aspin, and the birch, which they are careful to plant in the mud. These form their subsistence. Their magazines sometimes contain a cart-load of these articles, and the beavers are so industrious that they are always adding to their store."*

The nests so admirably constructed by what have been called the perfect societies of insects, the white ants or termites, the ants or formicæ, the bees, wasps, and humble bees, are well known, and have been often described. The materials used by the two first genera are chiefly clay, with bits of straw or wood, cemented by animal secretions; the bees manufacture wax for the purpose.

" The wasps and hornets are remarkable for the well-known curious papier-maché edifices, in the construction of which they employ filaments of wood, scraped from posts and rails with their own jaws, mixed with saliva, of which the hexagonal cells in which they rear their young are formed, and often their combs are separated and supported by pillars of the same material; and the external walls of their nests are formed by foliaceous layers of their ligneous paper." †

* Kirby, vol. ii. p. 510.
† Kirby, loc. cit. p. 335.

" The tree-ants, again, are remarkable for forming their nests on the boughs of trees of different kinds; and their construction is singular, both for the material and the architecture, and is indicative of admirable foresight and contrivance; in shape they vary from globular to oblong, the longest diameter being about ten inches, and the shortest eight. The nests consist of a multitude of thin leaves of *cow-dung*, imbricated like tiles upon a house, the upper leaf formed of one unbroken sheet covering the summit like a skull-cap. The leaves are placed one upon another in a wavy or scalloped manner, so that numerous little arched entrances are left, and yet the interior is perfectly secured from rain. They are usually attached near the extremity of a branch, and some of the twigs pass through the nest. A vertical section presents a number of irregular cells, formed by the same process as the exterior. Towards the interior the cells are more capacious than those removed from the centre, and an occasional dried leaf is taken advantage of to assist in their formation. The nurseries for the young broods in different stages of developement are in different parts of the nest."*

What is most peculiar in the habitations of all these " perfect societies of insects," is the formation, by the same working members of these societies, of cells of different size and form, suited for the different classes or ranks of individuals which, as we shall afterwards state, each of these associations comprises; and the occasional alteration of the size and form of the cells, when circumstances occur, which will be afterwards mentioned, to make an alteration of their destination advisable.

There are other examples among insects, of imperfect societies or associations, found temporarily and during the larva state only, which unite in forming tents under which they feed, and which shelter them from sun and rain. This is done by the larvæ of several species of butterfly and moth.†

4. The next instincts which may be noticed under this head are those connected with the *hybernation* of animals; for in almost every case in which this faculty (which is found so generally in the lower tribes, particularly reptiles and insects, as well as in the order Cheiroptera and several others of the higher animals,) exists, there is attached to it some instinctive propensity, prompting the animal, even although it be not one of those which form houses for themselves, at least to search for some suitable residence in which it may be sheltered during the winter, whether under ground, under stones or timber, under the bark of trees, &c.; and it is very remarkable that their hiding places are often found, or formed, long before the weather has become very cold. " I am led to believe from my own observation," says Mr. Spence, " that the days which the majority of coleopterous insects select for retiring to their hybernacula are some of the warmest days of autumn, when

* Ibid. p. 340.
† Spence and Kirby, vol. ii. p. 21.

they may be seen in great numbers alighting on walls, rails, path-ways, &c."* Some insects, and many larvæ (as the silk-worm) approaching to the state of pupæ, form a covering for themselves by exudations from their own bodies, likewise at some distance of time before the frosts set in. Many hybernating animals exhibit so little of any vital action as to require little or no nourishment during the winter, excepting the product of absorption of their own fat; but it is also well known that many of different orders (as the beaver, the hedgehog, the squirrel, the dormouse, the bee, which are seldom or never quite torpid,) are guided by instinct to lay up stores of provisions, on which they subsist during the winter. Some of these, as the lemming, have been observed to spread out their stores to dry in fine weather. Some of the most curious of the provisions of this kind are the following:—

"There is an animal, the *rat-hare*, which is gifted by its Creator with a very singular instinct, on account of which it ought rather to be called the *hay-maker*, since man may or might have learned that part of the business of the agriculturist, which consists in providing a store of winter provender for his cattle, from this industrious animal. Professor Pallas was the first who described the quadruped exercising this remarkable function, and gave an account of it. The Tungusians, who inhabit the country beyond the lake of Baikal, call it Pika, which has been adopted as its trivial name.

"About the middle of the month of August these little animals collect their winter's provender, formed of select herbs, which they bring near their habitations and spread out to dry like hay. In September they form heaps or stacks of the fodder they have collected under places sheltered from rain or snow. Where many of them have laboured together, their stacks are sometimes as high as a man, and more than eight feet in diameter. A subterranean gallery leads from the burrow below the mass of hay, so that neither frost nor snow can intercept their communication with it. Pallas had the patience to examine their provision of hay piece by piece, and found it to consist chiefly of the choicest grasses and the sweetest herbs, all cut when most vigorous, and dried so slowly as to form a green and succulent fodder; he found in it scarcely any ears or blossoms, or hard and woody stems, but some mixture of bitter herbs, probably useful to render the rest more wholesome."†

"Although," says Kirby, "ants during the cold winters in this country remain in a state of torpidity, and have no need of food, yet in warmer regions during the rainy seasons, when they are probably confined to their nests, a store of provisions may be necessary for them. Now although the rainy season, at least in America, is a season in which insects are full of life, yet the observation that ants may store up provisions in warm countries is confirmed by an account sent me by Colonel Sykes, with respect to another species which appears to belong to the same genus as the celebrated *ants of visitation*, by which the houses of the inhabitants of Surinam were said to be cleared periodically of their cock-roaches, mice, and even rats. The present species has been named by Mr. Hope the *provident ant*. These ants, after long-continued rains during the monsoon, were found to bring up and lay upon the earth on a fine day, their stores of grass seeds and grains of Guinea corn, for the purpose of drying them. Many scores of these hoards were frequently observable on the extensive parade at Poona."*

The great and important instinct of migration is another means by which the lives of many animals are preserved during winter. The number of species of birds, which pass the summer to bring forth their young in this country, but disappear from it in autumn, and are known to spend the winter in the south of Europe or Africa, has been stated at not less than five-sixths of the whole number resident here during the summer, and these are replaced by many other species, chiefly aquatic birds and waders, but likewise the fieldfares, redwings, starlings, &c. which have brought forth their young in the colder climates, and return here for the winter. There are others, as the crane and stork, which perform similar migrations, but are rarely seen in this country. The migrations of the larger birds from the northern regions are chiefly performed in large bodies, forming angular lines, very high in the air; those of the smaller birds of passage, swallows, singing birds, &c. that go southwards from hence, seem to take place less regularly, and have been less accurately observed. There are also many annual migrations from one part of this country to another, in spring and autumn, as of the plovers and lapwings, curlews, ring ouzels, &c. It is still doubtful with what sensations the propensity to perform these periodical migrations is chiefly connected, whether with changes of temperature, or deficiency of food, or with the changes of the sexual desire, (as maintained by Jenner.†) But it is certain that the migrations take place while the temperature is still such as is well borne by the animals; indeed of most of the species of birds of passage some individuals are frequently observed not to migrate;‡ and it is equally certain that most of the birds of passage do not gradually withdraw, as if following the gradual changes of the food on which they live, but go off suddenly, and perform their voyages, particularly in autumn, so rapidly, as to be much exhausted and emaciated at the end of them; so that it is certainly not under the influence of sensations gradually changing and tending to partial and successive changes of place, but under that of a strong determination, overcoming the motives to action which are usually predominant, and commanding strenuous and painful exertion at a time when no great inconvenience is felt, that these voyages are per-

* Introduction to Entomology, vol. ii. p. 438.
† Ib. p. 507.

* Vol. ii. p. 344.
† Phil. Trans. 1824.
‡ See Darwin, Zoonomia, sect. xvi. 12.

formed. And if, with Darwin and some others, we doubt of the existence of a blind instinctive propensity as the cause of these movements, we have no resource but to ascribe them to a very high degree of intelligence, combined with much mental resolution, and extending to all or almost all the individuals of the species, enabling them to foresee evils that are still remote, and determining them to undergo labour, fatigue, and danger in order to avoid them. It has also been repeatedly ascertained that the same individuals return after their six months of absence and long voyages, to the very spots where they had been brought forth, implying a power of discernment and recollection which appear to us quite inconceivable. Of such high qualities of mind we see no indications in the other actions of these birds, excepting only in their preparations for the nurture of their young; and if they really possessed these qualities, we might expect with perfect confidence to see them devise many contrivances for their comfort and convenience, and to witness variations and improvements in habits, which we know from the writings of the ancient naturalists to have been perfectly uniform and stationary at least since the time of Aristotle.

There are some of the Mammalia, chiefly of the order Ruminantia, which likewise perform periodical migrations in the natural state, as has been particularly noticed in America, of the bison, the musk-ox, and rein-deer. A similar instinct has been observed in the quaggas in Africa; and a singular observation, as shewing a variation of instinct according to varying circumstances, was made by Dr. Richardson, that the American black bear, when lean, and from that cause unfitted for hybernation, migrates in severe winters from the northward into the United States.

The periodical migrations of fishes appear to be designed for the benefit of their offspring, not for their own preservation; and there are other migrations, in immense numbers, of various kinds of animals which are not periodical, and of which the object is still obscure, but which do not fall under the present head.

II. *Of instincts for the propagation and support of offspring.*—Of the very curiously varied instincts of animals connected with the propagation and support of their offspring, we need not dwell on those which must necessarily attend the very various kinds of organs (so well arranged and described by Cuvier), by which the impregnation of the ova in the different tribes of animals is effected—the instincts, e. g. which prompt most male fishes to impregnate eggs already laid, and many reptiles to impregnate them at the moment of their emission from the body of the female, or which guide the different warm-blooded animals in the different modes of their sexual intercourse. The instincts which enable animals to anticipate and provide for the wants of their young are still more varied, and imply mental processes of greater complexity. The most important of these may be referred to the following heads.

1. This is probably one object of the migrations of birds above-mentioned, and certainly the main object of the migrations of great swarms of fishes, both in the sea, and of those which ascend the rivers; to which the same observations, as to the return to the same spot whence they had formerly departed, and as to the labours and hazard which the instinct impels them to incur, are in many instances applicable.

"The *cod-fish* makes for the coast at spawning time, going northward; this takes place towards the end of winter, or the beginning of spring.

"The *mackarel* hybernates in the Arctic, Antarctic, and Mediterranean Seas, where it is stated to select certain depths of the sea called by the natives Barachouas, which are so landlocked, that the water is as calm at all times as in the most sheltered pools.

"It is in these that the mackarel, directed by instinct, pass the winter. In the spring they emerge in infinite shoals from their hiding places, and proceed southward for the purposes of depositing their eggs in more genial seas.

"What the mackarel is to the north of Europe, the *thunny* is to the south. It deposits its eggs in May and June, when it enters the Mediterranean, seeking the shores in shoals arranged in the form of a parallelogram, or as some say, a triangle, and making a great noise and stir.

"The *herring* may be said to inhabit the arctic seas of Europe, Asia, and America, from whence they annually migrate at different times in search of food, and to deposit their spawn. Their shoals consist of millions of myriads, and are many leagues in width, many fathoms in thickness, and so dense that the fishes touch each other." "The largest and strongest are said to lead the shoals, which seem to move in a certain order, and to divide into bands as they proceed, visiting the shores of various islands and countries, and enriching their inhabitants." "They seek places for spawning where stones and marine plants abound, against which they rub themselves alternately on each side, all the while moving their fins with great rapidity."

"In temperate climates the *salmon* quits the sea early in the spring, when the waves are driven by a strong wind against the river currents." "They leave the sea in numerous bands formed with great regularity. The largest individual, which is usually a female, takes the lead, and is followed by others of the same sex, two and two, each pair being at the distance of from three to six feet from the preceding one; next come the old, and after them the young males in the same order." "They employ only three months in ascending to the sources of the Maraguon, the current of which is remarkably rapid, which is at the rate of nearly forty miles a day; in a smooth stream or lake their progress would increase in a four-fold ratio. Their tail is a very powerful organ, and its muscles have wonderful energy; by placing it in their mouth, they make of it a very elastic spring, for, letting it go with violence, they raise themselves in the air to the height of from twelve to fifteen feet, and so clear the cataract that impedes their course; if they fail in their first attempt, they continue their efforts till they have accomplished it. The female is stated to hollow out a long and deep excavation in the gravelly bed of the river to receive her spawn."*

A similar periodical emigration has been observed in other animals, particularly in some of the Crustacea.

"Several of the crabs forsake the waters for a time, and return to them to cast their spawn; but the most celebrated of all is that known by the name of *land-crab*, and alluded to by Dr. Paley as the violet-crab, and which is called by the French the *tourlourou*. They are natives of the West Indies and South America. In the rainy season, in May and June, their instinct impels them to seek the sea, that they may fulfil the great law of their Creator, and cast their spawn. They descend the mountains, which are their usual abode, in such numbers that the roads and woods are covered with them." "They are said to halt twice every day, and to travel chiefly in the night. Arrived at the sea-shore, they are there reported to bathe three or four times, when retiring to the neighbouring plains or woods, they repose for some time, and then the females return to the water, and commit their eggs to the waves. This business dispatched, they endeavour to regain, in the same order, the country they had left, and by the same route, but only the most vigorous can reach the mountains."†

The object of all these migrations is, that the female animals may have an opportunity of depositing their eggs where they will be in circumstances suited to their development, particularly as to the essential requisites, exposure to heat and to air.

2. The same object, the choice of a suitable place for depositing their eggs, is accomplished in other instances by very different instincts implanted in female animals. "Reptiles," says Kirby, "and Fishes do not feel the instinctive love for their young, after birth, which is exhibited by quadrupeds and birds, but are invariably instructed by the Creator to select a place in which their eggs can be hatched either by artificial or solar heat." Many of them likewise, as the salmon, dig holes before depositing them, for their protection. Those of the serpents which are not ovo-viviparous, bury their eggs in sand, or in heaps of fermenting matter. The Saurians also select a proper place for their eggs, the crocodile, e.g. the sands beside rivers; "one species of salamander commits a single egg to a leaf of Persicaria, protects it by carefully doubling the leaf, and then proceeding to another, repeats the manœuvre till her oviposition is finished. Toads and frogs lay their eggs in water, surrounded by a gelatinous envelope which forms the first nourishment of the embryo," corresponding to the albumen of the bird's egg.

In like manner every insect is directed by nature to place its eggs in situations where its young, when disclosed, will find its appropriate nourishment; some burrowing in the earth for this purpose; many flies in dead animal matter about to putrefy; many in different parts of living vegetables;* bees and ants in the cells where they are to be fed by the working members of their hives, &c. A species of the ichneumon fly and some of the wasps have been observed to bury caterpillars along with their eggs, on which their larvæ are to feed, and another fly to deposit its eggs on the back of a caterpillar, when the larvæ feed on the secretion by which the covering of the pupa is to be formed.†

3. The instincts called into action in the *nidification*, particularly of birds, are so numerous, varied, and admirably adapted to their purpose, as to have called forth admiration in all ages. The pairing of the parent birds at the beginning of spring, when the labour is to begin; the choice of a place suited to the habits of the species, on the ground, under ground, in rocks, on the edge of lakes or of the sea, in marshes, in bushes, on trees, on buildings of all descriptions; the choice of the materials, and the labour exerted for completing the work; some using clay, some sand, some moss, some leaves, some straw or twigs, some moss or lichen; many forming a rough outside of materials hardly to be distinguished from the surrounding objects, while the inside is warm and smooth; some building in very peculiar forms to impede the access to their young; the tailor-bird sewing leaves together with distinct stitches, and the Java swallows forming their gelatinous nests, as the bees manufacture their waxen cells, from the contents and secretions of their own stomachs;—all furnish proofs of contrivance too obvious and too nearly adjusted to varying circumstances, to have escaped the attention even of careless observers. Many of the Mammalia make some kind of provision, although less artificial, for the reception of their progeny. "Cats search about inquisitively for a concealed situation; burrowing animals retire to the bottom of their burrows, and several of the Rodentia make beds of their own hair to receive their young;" all beasts of prey, whose progeny come into the world blind and helpless, have some kind of retreat in which they supply them at once with warmth and nourishment. Many insects, also, besides those which associate in hives, use various precautions for the covering and protection of their eggs.

4. The instinct of *incubation*, which forms the next part of the provisions for the reproduction of birds, the extraordinary change then effected in the habits of the female bird, particularly when attended and cheered, as happens in so many cases, by the equally temporary instinct of song of the male bird,—is another natural phenomenon too striking and interesting to have escaped observation; and the object of

* Kirby, vol. i.

† Ibid.

* In this choice insects seem to be guided by the sense of smell, at least in the case where the food of the larvæ to be brought forth is different from that of the parent.

† Darwin.

this provision of nature has been fully elucidated by the observations of Reaumur and many others as to the efficacy of artificial heat in procuring the development of the chick.

5. The instincts of many parent animals are likewise the means adopted by nature for procuring *nourishment* for the young. This is observed as to those of the lower orders whose young are brought forth in circumstances rendering it impossible for them to procure their own food (as the bee and wasp), and also as to the carnivorous tribes, both of birds and quadrupeds; the exertion requisite for procuring their prey being beyond the power of the young animal, the instinct of the parent supplies the defect. In most cases fresh supplies of food are daily or even hourly brought to the young animals, but in some instances stores of nourishment are provided for the young of the higher animals, equally as for those of the bee or ant; the pelican brings a large supply in his pouch from a single fishing; and according to the observations of an author in the Magazine of Natural History, some of the carnivorous animals have the curious instinct of storing up with this view animals not dead, but stupified by injury of the brain. "I dug out," says he, "five young pole-cats, comfortably imbedded in dry withered grass; and in a side hole, of proper dimensions for such a larder, I poked out forty large frogs and two toads, all alive, but merely capable of sprawling a little. On examination I found that the whole number, toads and all, had been purposely and dextrously bitten through the brain."*

Lastly, the young of all warm-blooded animals being unable for some time after they come into the world to maintain their own temperature, would soon perish of cold, even if capable of procuring their own food, but for the *protection* they receive from their parents. This seems to be the most general final cause of the στοϱγη or maternal affection so strongly implanted in all these animals, and to which so much of the first period of the existence of their offspring is intrusted, but of which there is little trace in the lower tribes. As, however, the dangers to which these young animals are exposed are numerous and varied, so nature has provided against them, not by a propensity to the performance of one kind of action only, but by a vigilant and permanent feeling which controls all the habits of the parent animal, and prompts many actions, some of which are strictly instinctive, while others ought rather to be called voluntary, but are quite at variance with the ordinary habits of the animals. Every one must be aware of the increased ferocity given to the female carnivorous animals during the time that they are occupied with the care of their young, and of the resolution with which birds, at other seasons pacific and even timid, will resent any intrusion on their nests or young broods; of the provident care of the cat or the lioness, which carries her young in her mouth, and of almost all female warm-blooded animals, which gather them close to their bodies for protection from cold; of the anxiety of the hen which has sat on duck's eggs, when the ducklings take to the water; of the resolution and ingenuity with which the lapwing fixes on herself the attention of passengers who may come near her nest, &c. But what most distinctly indicates that all this care and anxiety are unconnected with any such anticipation of the results as would be acquired by a process of reasoning, is the absolute indifference which succeeds, when the parent animal at length sees her offspring independent of her assistance—

"And once rejoicing, never knows them more."

III. Various instinctive propensities may be observed in animals, the object of which is the advantage of the race or of the animal creation generally, rather than of the individual or his progeny, and some the object of which is still obscure. Some of these are, like the maternal affection last mentioned, obviously partaken by the human race, or even chiefly perceptible in those animals which have much connexion with man. The instinctive attachments not only of dogs but various domestic animals to their masters or attendants, of cats to houses, of sheep to particular hills or pastures, might be illustrated by many curious anecdotes, and seem to be very similar to the feelings which, after being fully developed in the human race, and strengthened and extended by the reflective powers of the human mind, obtain the names of family affection, of local attachment, of patriotism, &c. If the instinct of modesty exists in hardly any animals, the desire of cleanliness may be observed in many. The instinct of imitation, formerly noticed, and which is of so essential importance to all human enterprises in which the cooperation of numbers is required, is perhaps more distinctly observable in individual monkeys than in any other animals, although it is probable that a similar feeling may be part of the bond of association by which many animals are congregated together in the mode to be presently noticed. The intuitive perception of the signs of emotion or passion in the countenance and gestures which precedes and excites the tendency to imitation in man, is obviously common to us with many other animals.

In fact, although we rigidly maintain the essential superiority of the *intellect* of man over that of all other animals, we have already stated that the greater number of the *active* powers of the human mind which furnish the chief motives to action are on the same footing with those which operate on the lower animals. Not only are our appetites similar to theirs, but the greater number of the desires of which we are conscious are either shared with us by them, or at least would seem to belong to the same class as their instincts. Thus the desire of approbation is quite obvious at least in some of the domestic animals, and the desire of society, as observed by Stewart, seems to act very generally, although variously, in the animal creation. The desire of power may be thought to be more peculiar to man, and we

* Magazine, &c. vol. vi. p. 206.

have every reason to believe that no other animal can reflect on the possession of power in the abstract, or indulge in the imagination of scenes in which it is to be exerted, or rejoice in the acquisition of wealth of any kind, as the means of exercising power and procuring pleasure, independently of the actual enjoyment of them; but many of the practical exemplifications of this desire come into direct comparison with, and probably involve feelings very similar to, the instincts of animals. Thus the pleasure which men feel in exerting power over the elements around them may be seen, in the case of children, to be prior to the experience of any practical advantage from the arts of architecture, of mechanics, or of navigation; and it may be confidently asserted, that but for this pleasure attending the exercise of those arts (and which may be supposed to be very similar to that which animates the beaver, the bird, or the ant in their respective labours,) they could never have been prosecuted with success. So also the pleasure which man in all ages has felt both in hunting and destroying animals, and also in acquiring dominion over them and subjecting them to his power, is clearly quite different from the anticipation of the useful purposes to which, whether dead or living, they may be applied, and appears precisely similar, both in its nature and in its object or final cause, to some of the instincts of animals.

Indeed, in conformity to what has been already said of the essential peculiarities of the human intellect, it is only those motives to action which imply the previous formation of general notions or abstract ideas, that we can regard as peculiar to man; and we may accordingly state that the desire of knowledge (we may even say more specifically, of scientific knowledge, 'rerum cognoscere *causas*') and the sense of *obligation* religious and moral, are the motives to action which we believe to be truly peculiar to the human race.

The most important instinct of animals referable to this head, clearly and strongly felt likewise by man, (although combined in his case with many other feelings,) is the instinct of *congregation*. More or less of the desire of society is seen in a great majority of animals; but we may refer to this head many actions of animals, wherein many individuals of the same species cooperate, of which the object is in many instances still obscure, but to which the animals are impelled with an energy, and frequently a self-devotion, attesting the strength of the mental feeling, and completely superseding their usual habits. Messrs. Spence and Kirby enumerate not less than five kinds of association of insects to form what they term imperfect societies.

"The first of these associations (for the sake of company only) consists chiefly of insects in their perfect state. The little beetles called whirlwigs,—which may be seen clustering in groups under warm banks in every river and every pool, wheeling round and round with great velocity, at your approach dispersing and diving under water, but as soon as you retire resuming their accustomed movements,—seem to be under the influence of the social principle, and to form their assemblies for no other purpose than to enjoy together in the sunbeam the mazy dance. Impelled by the same feeling, in the very depth of winter, even when the earth is covered with snow, the tribes of *Tipulidæ* (usually but improperly called gnats) assemble in sheltered situations at mid-day where the sun shines, and form themselves into choirs that alternately rise and fall with rapid evolutions.

"Another association is that of males during the season of pairing. Of this nature seems to be that of the cockchafer and fernchafer, which, at certain periods of the year and hours of the day, hover over the summits of the trees and hedges like swarms of bees.

"The males of another root-devouring beetle (*Hoplia argentea*, F.) assemble by myriads before noon in the meadows, when in these infinite hosts you will not find a single female.

"The next description of insect associations is of those that congregate for the purpose of travelling or emigrating together. De Geer has given an account of the larvæ of certain gnats (*Tipulæ*, L.) which assemble in considerable numbers for this purpose, so as to form a band of a finger's breadth, and of one or two yards in length. And what is remarkable, while upon their march, which is very slow, they adhere to each other by a kind of glutinous secretion.

"Kuhn mentions another of the *Tipulidæ*, the larvæ of which live in society and emigrate in files.

"But of insect emigrants none are more celebrated than the locusts, which, when arrived at their perfect state, assemble in such numbers as in their flight to intercept the sun-beams and to darken whole countries, passing from one region to another, and laying waste kingdom after kingdom.

"The same tendency to shift their quarters has been observed in our little indigenous devourers, the Aphides.

"It is the general opinion in Norfolk, Mr. Marshall informs us, that the saw-fly (*Tenthredo*) comes from over sea. A farmer declared he saw them arrive in clouds so as to darken the air; the fishermen asserted that they had repeatedly seen flights of them pass over their heads when they were at a distance from land, and on the beach and cliffs they were in such quantities that they might have been taken up by shovels full. Three miles inland they were described as resembling swarms of bees.

"It is remarkable that of the emigrating insects here enumerated, the majority, for instance the Libellulæ, the Coccinellæ, Carabi, Cicadæ, &c. are not usually social insects, but seem to congregate, like swallows, merely for the purpose of emigration.

"The next order of imperfect associations is that of those insects which feed together.

"Two populous tribes, the great devastators of the vegetable world, the one in warm and the other in cold climates, to which I have already alluded under the head of emigrations,

—I mean *Aphides* and *Locusts*,—are the best examples of this order.

"So much as the world has suffered from these animals, it is extraordinary that so few observations have been made upon their history, economy, and mode of proceeding.

"The eggs of the locusts were no sooner hatched in June," says Dr. Shaw, "than each of the broods collected itself into a compact body, of a furlong or more in square, and then marching directly forwards towards the sea, they let nothing escape them; *they kept their ranks like men of war*, climbing over as they advanced every tree or wall that was in their way; nay, they entered into our very houses and bed-chambers like so many thieves. A day or two after one of these hordes was in motion, others were already hatched to march and glean after them. Having lived near a month in this manner they arrived at their full growth, and threw off their *nympha state* by casting their outward skin." "The transformation was performed in seven or eight minutes, after which they lay for a short time in a torpid and seemingly languishing condition; but as soon as the sun and the air had hardened their wings by drying up the moisture that remained on them after casting their sloughs, they re-assumed their former voracity with an addition of strength and agility."

"According to Jackson they have a government amongst themselves similar to that of the bees and ants; and when the king of the locusts rises, the whole body follow him, not one solitary straggler being left behind. But that locusts have leaders like the bees or ants, distinguished from the rest by the size and splendour of their wings, is a circumstance that has not yet been established by any satisfactory evidence; indeed, very strong reasons may be urged against it."

"The last order of imperfect associations approaches nearer to perfect societies, and is that of those insects which the social principle urges to unite in some common work for the benefit of the community.

"Many larvæ of *Lepidoptera* associate with this view, some of which are social only during part of their existence, and others during the whole of it.

"A still more singular and pleasing spectacle when their regiments march out to forage, is exhibited by the *Processionary Bombyx*. This moth, which is a native of France and has not yet been found in this country, inhabits the oak. Each family consists of from 600 to 800 individuals. When young, they have no fixed habitation, but encamp sometimes in one place and sometimes in another under the shelter of their web; but when they have attained two-thirds of their growth, they weave for themselves a common tent. About sun-set the regiment leaves its quarters; or, to make the metaphor harmonize with the trivial name of the animal, the monks their cœnobium. At their head is a chief, by whose movements their procession is regulated. When he stops all stop, and proceed when he proceeds; three or four of his immediate followers succeed in the same line, the head of the second touching the tail of the first; then comes an equal series of pairs, next of threes, and so on as far as fifteen or twenty. The whole procession moves regularly on with an even pace, each file treading on the steps of those that precede it. If the leader, arriving at a particular point, pursues a different direction, all march to that point before they turn."*

Examples of occasional associations, more or less resembling all these, and of which the object is in many instances still obscure, may be found in all the classes of the higher animals, as is obvious, when we consider to how many tribes of animals the term *gregarious* is usually applied, e. g. to almost all the Ruminantia, some of the Pachydermata, and a few of the Rodentia. Some of the genus Muridæ (rats and mice) have been long known to migrate, occasionally, in a manner resembling the locusts. "The general residence of the lemming," says Pallas, "is in the mountainous parts of Lapland and Norway, from which tracts at uncertain periods it descends in immense troops, and by its incredible numbers becomes a temporary scourge to the country, devouring the grain and herbage, and committing devastations equal to those of an army of locusts." "It is observable that their chief emigrations are made in the autumns of such years as are followed by severe winters." "The ground over which they have passed appears at a distance as if it had been ploughed, the grass being devoured to the roots in numerous stripes or parallel paths, of one or two spans broad, and at the distance of some yards from each other." "The army moves chiefly at night, or early in the morning. No obstacles that they meet in their way have any effect in altering their route, neither fires, nor deep ravines, nor torrents, nor marshes, nor lakes; they proceed obstinately in a straight line, and hence many thousands perish in the waters." "If disturbed, in swimming over a lake, by oars or poles, they will not recede, but keep swimming directly on, and soon get into regular order again." "In their passage over land, if attacked by men, they will raise themselves up, uttering a kind of barking sound, and fly at the legs of their invaders, and will fasten so fiercely on the end of a stick, as to suffer themselves to be swung about without quitting their hold, and are with great difficulty put to flight." "The major part of these hosts is destroyed by various enemies, as owls, hawks, weasels, exclusively of the number that perish in the waters, so that but a small part survive to return, as they are sometimes observed to do, to their native mountains." The campagnol, or short-tailed rat, has been known to commit similar ravages in France. It is obvious here, that under the influence of this instinct, and of the excitement of numbers (in which, as in our own race, the principle of imitation is probably much concerned) the usual motives to action of these animals are superseded, and their usual habits changed.

We are still uncertain as to the use, or final

* Introduction to Entomology, letter xvi.

cause, of the various congregations of birds that we daily witness, and of the varying habits which they then exhibit—crows, e. g. herons, and many water birds, roosting and bringing forth their young in large irregular societies; the crows, besides, assembling at particular hours of the day, at all seasons; some of the genus Parus, particularly the great and long-tailed titmouse, feeding in small flocks at all seasons;—plovers and lapwings keeping separate during the season of hatching and rearing their offspring, but assembling in flocks after their young have attained maturity;—most of the birds of this country in the depth of winter associating in flocks much greater than can be necessary for the sake of warmth;—the hen chaffinches, and perhaps the females of other birds, congregating separately;—many of these flocks consisting of multitudes moving quite irregularly, but all of them having apparently some means of intercommunication or agreement;—some of them, as the starlings, performing very singular evolutions in concert; and many, as wild geese and other water-birds, always showing the disposition to fly in regular lines.

The greatest of all the congregations of birds are those of the migrating pigeons in America, described by Audubon, as forming clouds which pass over the whole extent of a town for several hours together, and as settling on extensive districts of the woods in such multitudes as to cause much devastation among the branches.

But the most extraordinary of all the associations of animals are those which have received the title of the perfect societies of insects,—the bees, wasps, hornets and ants in the order of Hymenoptera, and the white ants or termites, in that of Neuroptera. The most important facts as to them seem to have been ascertained, partly by numerous former observers, but chiefly by the Hubers, Latreille, and others in the present age.

The essential peculiarity of these associations of insects appears to be the complete separation of the males and females, on whom the propagation of the species depends, from the working members of the communities, by whom the habitations are constructed, and who procure food both for the young and for the more perfect insects. In the case of the bees, the only prolific female is the queen-bee; the males are the drones; the working bees, constituting the mass of the community, are sterile females, and the larvæ and pupæ are confined to the cells and helpless; the ants appear to differ from these only in the perfect females being much more numerous (only a few, however, being retained in each ant-hill); but the termites differ, in the larvæ and even the pupæ being working members, the males and females, when brought to perfection, always wandering abroad, and one of each sex in the perfect state only existing in each nest, being in fact forcibly detained there.

Among these animals there is also a separate class, believed to be analogous to the working bees, i. e. to be sterile females, larger than the labourers, and which are thought to act exclusively as the soldiers of the community,—the smaller working ants (larvæ) always disappearing, and these larger and fiercer animals shewing themselves, when any of the works are attacked.*

These associations differ from all others existing among animals, in the extraordinary instinct of respect and devotion shewn by the working members to the impregnated female,—single in each swarm of bees, and in each nest of termites, and few in number in each nest of ants,—and with this instinct most of their other peculiarities seem to be connected.

But it is justly observed by Mr. Spence, that if we suppose all the labours of the bees and the ants to be guided by instincts, we must necessarily attribute to these animals a much greater number and variety of instinctive propensities, and more extraordinary modifications of them to suit varying circumstances of their condition, than to any of what are usually called the higher animals.

"In the common duck, one instinct leads it at its birth from the egg to rush to the water; another to seek its proper food; a third to pair with its mate; a fourth to form a nest; a fifth to sit upon its eggs till hatched; a sixth to assist the young ducklings in extricating themselves from the shell; and a seventh to defend them when in danger until able to provide for themselves: and it would not be easy as far as my knowledge extends, to add many more instinctive actions to the enumeration, or to adduce many specimens of the superior classes of animals endowed with a greater number.

"But how vastly more manifold are the instincts of the majority of insects!

"As the most striking example of the whole, I shall select the hive-bee,—begging you to bear in mind that I do not mean to include those exhibited by the queen, the drones, or even those of the workers, termed by Huber *cirières* (wax-makers); but only to enumerate those presented by that portion of the workers, termed by Huber *nourrices* or *petites abeilles*, upon whom, with the exception of making wax, laying the foundation of the cells, and collecting honey for being stored, the principal labours of the hive devolve.

"By one instinct bees are directed to send out scouts previously to their swarming in search of a suitable abode; and by another to rush out of the hive after the queen that leads forth the swarm, and follow wherever she bends her course. Having taken possession of their new abode, whether of their own selection or prepared for them by the hand of man, a third instinct teaches them to cleanse it from all impurities; a fourth to collect propolis, and with it to stop up every crevice except the entrance: a fifth to ventilate the hive for preserving the purity of the air; and a sixth to keep a constant guard at the door.

"In constructing the houses and streets of their new city, or the cells and combs, there are probably several distinct instincts exercised;

* See Spence and Kirby, vol. ii. p. 39.

but not to leave room for objection, I shall regard them as the result of one only: yet the operations of polishing the interior of the cells, and soldering their angles and orifices with propolis, which are sometimes not undertaken for weeks after the cells are built; and the obscure but still more curious one of varnishing them with the yellow tinge observable in old combs, seem clearly referable to at least two distinct instincts.

"In their out-of-door operations several distinct instincts are concerned. By one they are led to extract honey from the nectaries of flowers; by another to collect pollen after a process involving very complicated manipulations, and requiring a singular apparatus of brushes and baskets; and that must surely be considered a third which so remarkably and beneficially restricts each gathering to the same plant. It is clearly a distinct instinct which inspires bees with such dread of rain, that even if a cloud pass before the sun, they return to the hive in the greatest haste.

"Several distinct instincts, again, are called into action in the important business of feeding the young brood. One teaches them to swallow pollen, not to satisfy the calls of hunger, but that it may undergo in their stomach an elaboration fitting it for the food of the grubs; and another to regurgitate it when duly concocted, and to administer it to their charge, proportioning the supply to the age and condition of the recipients. A third informs them when the young grubs have attained their full growth, and directs them to cover their cells with a waxen lid, convex in the male cells, but nearly flat in those of workers, and by a fourth, as soon as the young bees have burst into day, they are impelled to clean out the deserted tenements and make them ready for new occupants.

"Numerous as are the instincts already mentioned, the list must yet include those connected with that mysterious principle which binds the working bees of a hive to their queen:—the singular imprisonment in which they retain the young queens that are to lead off a swarm, until their wings be sufficiently expanded to enable them to fly the moment they are at liberty, gradually paring away the waxen wall that confines them to an extreme thinness, and only suffering it to be broken down at the precise moment required;—the attention with which in these circumstances they feed the imprisoned queen by frequently putting honey on her proboscis, protruded from a small orifice in the lid of her cell;—the watchfulness with which, when at the period of swarming more queens than one are required, they place a guard over the cells of those undisclosed, to preserve them from the jealous fury of their excluded rivals;—the exquisite calculation with which they invariably release the *oldest* queens the first from their confinement;—the singular love of monarchical dominion, by which, when two queens in other circumstances are produced, they are led to impel them to combat until one is destroyed;—the ardent devotion which binds them to the fate and fortune of the survivor;—the distraction which they manifest at her loss, and their resolute determination not to accept of any stranger until an interval has elapsed sufficiently long to allow of no chance of the return of their rightful sovereign;—and (to omit a further enumeration) the obedience which in the utmost noise and confusion they shew to her well-known hum.

"I have now instanced at least thirty distinct instincts with which every individual of the nurses amongst the working-bees is endowed; and if to the account be added their care to carry from the hive the dead bodies of any of the community; their pertinacity in their battles, in directing their sting at those parts only of the bodies of their adversaries which are penetrable by it; their annual autumnal murder of the drones, &c. &c.—it is certain that this number might be very considerably increased, perhaps doubled."*

To these instincts, in the case of some species of ants we shall certainly have to add those by which they are guided in carrying on a regular system of warfare, either with other hives of the same species or with other species, in subjugating and bringing up as workers or slaves those that they have subdued, and likewise in subjecting to their dominion tribes of Aphides.†

But all this becomes still more surprising, because more at variance with the usual instincts of animals, when we consider the power of adapting their operations to changes in their circumstances, which such associations of insects possess.

"It is," says Mr. Spence, "in the *deviations* of the instincts of insects and their *accommodation to circumstances*, that the exquisiteness of these faculties is most decidedly manifested. The instincts of the larger animals seem capable of but slight modification. They are either exercised in their full extent or not at all. A bird, when its nest is pulled out of a bush, though it should be laid uninjured close by, never attempts to replace it in its situation; it contents itself with building another. But insects in similar contingencies often exhibit the most ingenious resources, their instincts surprisingly accommodating themselves to the new circumstances in which they are placed, in a manner more wonderful and incomprehensible than the existence of the faculties themselves."

This observation we support by various instances taken from the history of different insects; but the most extraordinary are from the societies of insects of which we now speak; and of these the following are only a specimen.

"The combs of bees are always at an uniform distance from each other, namely, about one-third of an inch, which is just wide enough to allow them to pass easily, and have access to the young brood. On the approach of winter, when their honey-cells are not sufficient in number to contain all the stock, they *elongate* them considerably, and thus increase their capa-

* Introduction to Entomology, vol. ii. p. 498 et seq.

† Introd. to Entomology, letter xvii.

city. By this extension the intervals between the combs are unavoidably contracted; but in winter well-stored magazines are essential, while from their state of comparative inactivity spacious communications are less necessary. On the return of spring, however, when the cells are wanted for the reception of eggs, the bees contract the elongated cells to their former dimensions, and thus re-establish the just distances between the combs which the care of their brood requires. But this is not all. Not only do they elongate the cells of the old combs when there is an extraordinary harvest of honey, but they actually give to the new cells which they construct on this emergency, a much greater *diameter* as well as a greater depth.

"The queen-bee, in ordinary circumstances, places each egg in the centre of the pyramidal bottom of the cell, where it remains fixed by its natural gluten: but in an experiment of Huber, one whose fecundation had been retarded, had the first segments of her abdomen so swelled that she was unable to reach the bottom of the cells. She therefore attached her eggs (which were those of males) to their lower side, two lines from the mouth. As the larvæ always pass that state in the place where they are deposited, those hatched from the eggs in question remained in the situation assigned them. But the working bees, as if aware that in these circumstances the cells would be too short to contain the larvæ when fully grown, *extended their length,* even before the eggs were hatched.

"The working bees, in closing up the cells containing larvæ, invariably give a convex lid to the large cells of drones, and one nearly flat to the smaller cells of workers; but in an experiment instituted by Huber to ascertain the influence of the size of the cells on that of the included larvæ, he transferred the larvæ of workers to the cells of drones. What was the result? Did the bees still continue blindly to exercise their ordinary instinct? On the contrary, they now placed a nearly *flat* lid upon these large cells, as if well aware of their being occupied by a different race of inhabitants."

But the most extraordinary of all these variations of the operations of bees are seen in two cases which have been often produced for the sake of experiment, and of which the result appears to have been repeatedly and carefully observed.

"If a hive be in possession of a queen duly fertilized, and consequently sure, the next season, of a succession of males, all the drones, towards the approach of winter, are massacred by the workers with the most unrelenting ferocity. This would seem to be an impulse as naturally connected with the organization and very existence of the workers, as that which leads them to build cells or store up honey. But however certain the doom of the drones if the hive be furnished with a duly fertilized queen, their undisturbed existence through the winter is equally certain if the hive has lost its sovereign, or if her impregnation has been so retarded as to make a succession of males in the spring doubtful; in such a hive the workers do not destroy a single drone, though the hottest persecution rages in all the hives around them."

Again, "in a hive which no untoward event has deprived of its queen, the workers take no other active steps in the education of her successors,—those of which one is to occupy her place when she has flown off at the head of a new swarm in spring,—than to prepare a certain number of cells of extraordinary capacity for their reception while in the egg, and to feed them when become grubs with a peculiar food until they have attained maturity. This, therefore, is their ordinary instinct; and it may happen that the workers of a hive may have no necessity, for a long series of successive generations, to exercise any other. But suppose them to lose their queen. Far from sinking into that inactive despair which was formerly attributed to them, after the commotion which the rapidly-circulated news of their calamity gave birth to has subsided, they betake themselves with an alacrity from which man, when under misfortune, might deign to take a lesson, to the reparation of their loss. Several ordinary cells are without delay pulled down and converted into a variable number of royal cells, capacious enough for the education of one or more queen-grubs selected out of the unhoused working grubs—which in this pressing emergency are mercilessly sacrificed—and fed with the appropriate royal food to maturity. Thus sure of once more acquiring a head, the hive return to their ordinary labours, and in about sixteen days one or more queens are produced, one of which steps into day and assumes the reins of state."

There can be no doubt that the perfect order and regularity seen in all the operations of these societies of insects could not be maintained without some mode of communication among the different individuals concerned in these operations; and it appears distinctly that such means of communication exist, and that it is in consequence of their being exercised, for example, that a swarm of bees, when it leaves a hive, takes the direction to a spot previously fixed on, and carefully examined, by a small number of scouts, as observed by Mr. Knight.*

When such facts are duly considered, we cannot be surprised to find so intelligent a naturalist as Mr. Spence acknowledging that he had at one time arranged them as indications of reason in these animals. But on further consideration, we shall probably see cause to acquiesce in his later and more matured judgment, which ascribes them to strictly instinctive, although singularly varying propensities; chiefly on two grounds, which exactly correspond to what was stated in the beginning of this paper as the most distinctive characters of instinct: 1. that although various contrivances are fallen on by *all* bees to enable them to continue their usual operations under varying external circumstances, yet there is no such variety observed either in the conduct of individuals

* Phil. Trans. 1807.

of the species or in the conduct of different communities, as we cannot doubt must occur if the inhabitants of every hive were guided, on such unusual occasions, by processes of reasoning, by observation of the laws of nature, by experience, and anticipation of the effects of their actions. If such mental processes were their guide, we should certainly observe a difference in the conduct of experienced workers, and of those just emerged from their pupæ; and we should observe some variety in the expedients adopted in different hives for meeting such accidents or difficulties. 2. While the varying operations of these animals for one particular end, the preservation of their own lives and the perpetuation of their species, are planned and combined in such a manner as to indicate consummate intelligence as to what is essential for that purpose, all these indications of instinct are limited to that object, and we see no evidence of the exercise of their senses suggesting to them any other trains of thought, or exciting them to the prosecution of other objects, such as a number of human intellects capable of planning and executing such works would certainly, sooner or later, attempt to accomplish. The degree of uniformity seen in their operations, and the limitation of the objects on which their faculties are exerted, are therefore our reason for thinking (although we do not wish to express ourselves with absolute confidence on the subject) that the mental processes concerned, even in those the most elaborate and artificial of the works of animals, belong to the same class as those notions of man which are prompted by his instinctive propensities as distinguished from his reason.

At the same time it ought to be stated, that there are many acts of individual animals, or of particular communities, in which we must admit that, although instinct is concerned, it must be guided by mental operations, in which short processes of reasoning, involving certain general ideas, must have been concerned. Several instances, quoted by Mr. Spence, seem hardly to admit of any other interpretation, e.g. the following from Huber. The bees of some of his neighbours protected themselves against the attacks of the death's-head moth, (Sphinx atropos,) by so closing the entrance of the hive with walls, arcades, &c. built of a mixture of wax and propolis, that these marauders could no longer intrude themselves. Pure instinct would have taught "the bees to fortify themselves on the *first* attack; if the occupants of a hive had been taken unawares by these gigantic aggressors one night, on the second at least the entrance should have been barricadoed. But it appears clear, from the statement of Huber, that it was not until the hives had been *repeatedly attacked*, and robbed of nearly their whole stock of honey, that the bees betook themselves to the plan so successfully adopted for the security of their remaining treasures; so that reason, taught by experience, seems to have called into action their dormant instinct."

Again, "a German artist, a man of strict veracity, states that in his journey through Italy he was an eye-witness to the following occurrence. He observed a species of Scarabæus busily engaged in making, for the reception of its egg, a pellet of dung, which when finished it rolled to the summit of a small hillock, and repeatedly suffered to tumble down its side, apparently for the sake of consolidating it by the earth which each time adhered to it. During this process the pellet unluckily fell into an adjoining hole, out of which all the efforts of the beetle to extricate it were in vain. After several ineffectual trials, the insect repaired to an adjoining heap of dung, and soon returned with three of his companions. All four now applied their united strength to the pellet, and at length succeeded in pushing it out; which being done, the three assistant beetles left the spot and returned to their own quarters."*

A number of other instances have been collected by Mr. Duncan.

"Professor Fischer has published an account of a hen, which hen made use of the artificial heat of a hotbed to hatch her eggs."

"A fact is stated by Reaumur of some ants, which, finding they could derive heat from a bee-hive, contrived to avail themselves of it by placing their larvæ between the hive and an exterior covering."

"Dr. Darwin observed a wasp with a large fly nearly as big as itself; finding it too heavy, it cut off the head and the abdomen, and then carried off the remainder, with the wings attached to it, into the air: but again finding the breeze act on the wings, and impede its progress, it descended, and deliberately cut off the wings. Instinct might have taught it to cut off the wings of all insects previous to flying away with them; but here it attempted to fly with the wings on, was impeded by a certain cause, discovered what that cause was, and alighted to remove it. Is not this a comparison of ideas, and deducing consequences from premises?"

"M. de la Loubière, in his relation of Siam, says, that in a part of that kingdom which lies open to great inundations, all the ants make their settlements on trees; no ants' nests are to be seen any where else. Whereas in our country the ground is their only habitation."

"We sometimes kill a cockroach," says Ligon in his history of Barbadoes, quoted by Spence, "and throw him on the ground, and mark what the ants will do with him; his body is bigger than a hundred of them, and yet they will find the means to lay hold of him and lift him up; and having him above ground, away they carry him; and some go by as ready assistants if any be weary, and some are officers that lead and shew the way; and if the van-couriers perceive that the body of the cockroach lies across, and will not pass through the hole or arch through which they mean to carry him, order is given, and the body turned endways, and this is done a foot before they come to the hole, and without stop or stay."†

* Introd. to Entomology, vol. ii. p. 525.
† History of Barbadoes, p. 63.

Colonel Sykes communicated to Mr. Kirby a singular anecdote of some of the black ants in India, which had been prevented, for some time, from getting to some sweatmeats, by having the legs of the table on which they stood immersed in basins filled with water, and besides painted with turpentine. After a time, however, the ants again reached the sweatmeats; and it was found that they did so by letting themselves drop from the wall, above the table, on the cloth which covered it.*

"In Senegal, where the heat is great, the ostrich neglects her eggs during the day, but sits on them at night. At the Cape of Good Hope, however, where the degree of heat is less, the ostrich, like other birds, sits upon her eggs both day and night."

"Rabbits dig holes in the ground for warmth and protection; but after continuing long in a domestic state, that resource being unnecessary, they seldom burrow."

"A dog in a monastery, perceiving that the monks received their meals by rapping at a buttery-door, contrived to do so likewise, and when the allowance was pushed through, and the door shut, ran off with it. This was repeated till the theft was detected."

"A dog belonging to Mr. Taylor, a clergyman, who lived at Colton, near Wolseley Bridge, was accused of killing many sheep. Complaints were made to his master, who asserted that the thing was impossible, because he was muzzled every night. The neighbours persisting in the charge, the dog one night was watched, and he was seen to draw his neck out of the muzzle, then to go into a field, and eat as much of a sheep as satisfied his appetite. He next went into the river to wash his mouth, and returned afterwards to his kennel, put his head into the muzzle again, and lay very quietly down to sleep."

"I observed," says the Rev. J. Hall in his Travels in Scotland, "two magpies hopping round a gooseberry bush, in a small garden near a poor-looking house, in a peculiar manner, and flying in and out of the bush. I stepped aside to see what they were doing, and found from the poor man and his wife, that as there are no trees all around, these magpies several succeeding years had built their nest, and brought up their young, in this bush; and that foxes, cats, hawks, &c. might not interrupt them, they had barricadoed not only their nest, but had encircled the bush with briers and thorns in a formidable manner; nay, so completely, that it would have cost even a fox, cunning as he is, some days' labour to get into that nest.

"The materials in the inside of the nest were soft, warm, and comfortable; but all on the outside, so rough, so strong, and firmly entwined with the bush, that without a hedge-knife, hatch-bill, or something of the kind, even a man could not, without much pain and trouble, get at their young; as from the outside to the inside of the nest extended as long as my arm.

"These magpies had been faithful to one another for several summers, and drove off their young, as well as every one else who attempted to take possession of their nest. This they carefully repaired and fortified in the spring with strong rough prickly sticks, that they sometimes brought to it by uniting their force, one at each end, pulling it along, when they were not able to lift it from the ground."*

Such examples leave no reasonable ground for doubt, that on certain subjects at least some animals are capable of short and simple processes of reasoning or of imagination, which appear to imply the perception of general truths, and the formation of certain general ideas, and that the difference, formerly stated between the operations of their minds and ours, in that respect, is one of degree only, not absolutely of kind. But this admission, it must be remembered, does by no means diminish the force of the considerations formerly adduced to establish the essential distinction between the instinctive determinations prompting the usual actions of animals, and some of those of men, and those volitions, whether in animals or men, which are consequent on the exercise of reason, and on such anticipation of their consequences as a process of reasoning only can afford.

It is worth while to mention that in some instances animals have been thought to be possessed of a faculty resembling reason, on account of actions, very wonderful indeed, but which the possession of reason would not have enabled them to perform. Thus there are many instances of animals finding their way to their usual place of residence, after being removed from it in such a way as to prevent the mere act of recollection guiding them back. Mr. Duncan† mentions having seen a pigeon, which had been brought from London, let loose on Magdalen Bridge, in Oxford. "It flew first towards the north, but after several gyrations in the air, it flew directly east, and reached London within the appointed time, which was, I believe, three hours." And Mr. Spence gives an anecdote, well authenticated, of an ass from Gibraltar, thrown overboard from a vessel at a distance of 200 miles, which swam ashore, and in a few days afterwards presented himself for admission when the gate of the fortress was opened in the morning. Two instances, equally extraordinary, have been stated on unexceptionable authority to the present writer; one of a pointer which had been sent from Durham to the neighbourhood of Edinburgh by sea, and made his way back in a few days by land, to his master's house in the former county;—the other of a kitten, which had been brought in a carriage a distance of above forty miles, to Edinburgh, and made its way back in a few days to its place of nativity in Stirlingshire, in doing which it must have crossed several bridges. Similar facts have been ascertained in several instances as to sheep; and the cases of the swallow and of the

* Bridgewater Treatise, vol. ii. p. 342.

* Duncan's Lectures on Instinct.

† Ibid.

salmon, returning to the spots where they were bred after their long migrations, are clearly analogous.

But in such cases it is obvious that the possession of reason could not have enabled these animals, alone and unassisted, to find their way; neither was the result properly referable to instinct, this term being properly applicable only to the feeling of attachment which prompted the return home, not to the knowledge which the animals somehow acquired where their home was to be found. The only term properly applicable to the acquisition of this knowledge is *intuition*, and they should be added to other facts, which shew that in various instances animals acquire, by the exercise of their senses, information as to external things, more obviously distinct from the sensations themselves, than those perceptions which Dr. Reid has so clearly shewn to be strictly intuitive inferences, drawn by the human intellect from the intimations of the senses.

There is yet another fact well ascertained of late years regarding the instincts of animals, which we must not omit to state, because it is the only one which gives plausibility to the notion of Darwin, that sensations and experience would explain the whole phenomena of instinct. This is the fact, which seems well ascertained as to certain animals at least,—which is very probably true of man, and susceptible of important practical application in his case,—that the acquired habits of one generation may become instinctive propensities in the next. Thus it has been often observed that the progeny of well-trained pointers learn to point with very little instruction. It is stated by Darwin that dogs in the wild state, both in Africa and America, have been observed not to bark, that they gradually acquire that note from European dogs; and that the latter, when turned loose, retain it for three or four generations, and gradually lose it; and it has been ascertained that in South America, when horses which had been taught to amble had been allowed to run wild, their progeny for two or three generations continued to practice that pace, and then lost it.* Of the existence of such *acquired* instincts, therefore, there can be no doubt; but it need hardly be said that it is quite incompetent to explain the perfect uniformity and the skilful contrivance observed in the instincts of animals; both because its operation seems too limited, and because that supposition would only remove the difficulty as to the continuance of the instinctive operations from the present to the early generations of animals.

In reviewing the varied phenomena of which we have given this hasty sketch, it is impossible not to be struck with the very important share which they occupy in the provisions by which the earth's surface is made a scene of continual activity and change. It is interesting to reflect on the different powers, to the operation of which we can trace the unceasing changes continually taking place around us, and particularly on the gradation, and very gradual transition that may be observed, from those by which inanimate matter is continually moved and changed, up to those which emanate from the intellect of man. By the original impulse given to the world, and by the laws of gravitation and of motion impressed on all matter, the greater and more striking movements of the inanimate world around us are continually determined; and by the laws of chemistry, these movements are made subservient to constant changes in the composition of the inanimate world. Again, by the laws which were impressed on the lower class of living beings at the time of their introduction into the world, and by the consequently incessant reproduction of vital affinities, which it is in vain to attempt to resolve into the chemistry of dead matter, a constant succession of living vegetable structures is determined, merely by the agency of air and water, heat and light, on those already existing. By the peculiar chemical operation of these living structures, the air, the water, and all the materials of the earth's surface are subjected to peculiar and continual changes, implying slow but incessant movements, which seem clearly to indicate attractions and repulsions, peculiar to the state of vitality. It is still perhaps doubtful whether in the case of vegetables a property of vital contraction is to be added to the active powers of nature. In immediate but still obscure connection with the lowest of the vegetable creation are the lowest of the animals, where we see the first and slightest indications of sensations, and the feeblest motions consequent on sensations, which we judge to be similar to those that we ourselves experience and excite; and here also the vital power of contraction, on which the whole life and activity of animals essentially depends, first clearly manifests itself. Then tracing the animal creation upwards, we find that the world contains an infinite number and variety of sentient beings, the provisions for whose enjoyment we may well believe to have been the main object of Providence in all the arrangements on the surface of the earth; and to which are granted, in a pretty uniform gradation, more and more of the sensations and mental faculties by which nature is made known, and of the powers by which she may be controlled, until we arrive at the intellect and the capacity of Man.

It appears farther that the maintenance, and reproduction, and the very existence of these animal structures are entrusted in part to the sensations of which they are made susceptible, and to the voluntary powers with which they are invested; but that the introduction of these spontaneous powers into the regulation of their œconomy is so very gradual, that it is hardly possible to say where the movements which result only from physical (although vital) causes terminate, and those which are excited by mental acts begin;—hardly possible, for example, to say, at least as to many animals,

* This principle has been lately investigated and illustrated by Mr. Knight, in a paper read before the Royal Society of London.

whether the reflex function of Dr. Marshall Hall, on which respiration, deglutition, the evacuation of the bowels and bladder, &c. depend, is to be regarded as the result of a merely *physical* impression on the nerves and spinal cord, like the impression of blood on the heart; or whether the *sensations* which naturally accompany these actions are, in the natural state, part of the cause which excites them. But that even when the voluntary powers of animals are certainly the means employed for the ends of their creation, they are still very generally guided by the superior intelligence which has framed both their physical and mental constitution, and which rules the mental but instinctive efforts consequent on the sensations that are felt, as surely as the laws of muscular contraction rule the movements of the heart; and it is into the hands of man alone that the reins of voluntary power are absolutely resigned.

And when we thus pass in review the sensorial and voluntary powers of animals, we are naturally led to the question, whether there is really in our own case so great an exception to those laws of nature which regulate all the other members of the animal creation; whether, admitting the essential superiority of the intellect or reason of man, the different desires and motives to action, which are implanted in him, are not equally subject to the control of the power that gives them, and whether their consequences are not as exactly ruled by laws and as fully anticipated, as those of the instincts of animals.

Without entering fully on this abstruse question, we would take the liberty of remarking, in the view of placing it in its simplest form before our readers, that as the intimations of our own consciousness are the ultimate foundation of all the knowledge that we have or can have of our own minds, and as *certain* of the intuitive principles of belief which our minds naturally suggest to us *must* be trusted, if we are to inquire into the subject at all; so the only question that can be reasonably proposed on this point is, whether there is any good reason for suspecting that the belief of our own free-will, which naturally attends certain of the operations of our minds, is a deception; and that the analogy of other animals is only applicable to the subject in so far as it can throw light on that question.

Now, we find that the works of man, which we ascribe to his reason, and in the execution of which the consciousness of his free-will intervenes, are *essentially different* from those which we ascribe to the blind instincts of animals, in the total absence (already noticed) of that *uniformity* which is so leading a characteristic of the effects of the latter; and we may reasonably assert that this is just the difference to be expected between the works of man and of other animals, on the supposition that the power concerned in the former is not subject to the direct influence and control of that higher intellect, by which the laws and limits of that concerned in the latter are irrevocably set; and therefore, that there exists no such analogy between the works of man and of other animals as need induce us to suspect, that the evidence of his consciousness on the point in question is not to be trusted.

At the same time it ought to be observed, and perhaps has not been duly remarked, not only that the desires which are the principal motives to human action, are analogous to, sometimes identical with, the instincts of animals, (many of them having been evidently given him with the same intention, and with a clear perception of their *general* result on his condition,)—but also that the constitution of the human mind appears from the intimations of our own consciousness to be such, as to allow of interposition of a superior power, controlling in a certain degree the will of man, without making itself obvious to his mind. For it is admitted by the soundest metaphysicians, that the only truly voluntary power which we are conscious of possessing over the train of thought in our minds, and therefore ultimately over many of our actions, operates only *indirectly*.* We have no power of determining the thoughts that succeed one another or regulating the order of their succession; and although various laws of association have been laid down, by which many of the component parts of the train appear to be connected, yet it will hardly appear to any one who reflects on the operations of his mind, that *all* the thoughts which succeed one another can be ascertained to have such bonds of connection with one another. At all events, the only strictly voluntary power which we are conscious that we possess, is that of singling out and detaining any particular portion of the train, whereby it may be made to predominate in the mind, and to produce practical results which might not otherwise have followed; and even this kind of influence over the train of thought is not exercised exclusively by volition, but is produced in a great measure also by other causes, physical and moral. Now if this be so, how can we deny the possibility of a superior intelligence retaining a power of controlling the acts of any individual human mind, or of any number of minds, either by suggesting particular thoughts, or by causing the mind to dwell upon particular thoughts in preference to others, without its sense of its own voluntary power being interrupted or withdrawn,—nay, without the spontaneous voluntary power being really suspended, the only difference being in the *degree* of influence which it exerts over the train of thought and consequent volitions?

It has been said that the expression in Pope's Universal Prayer—

* "So completely is the current of thoughts in the mind," says Stewart, "subjected to physical laws, that it has been justly observed by Lord Kames that we cannot, by an effort of our will, call up any one thought, and that the train of our ideas depends on causes which operate in a manner inexplicable by us. This observation, although it has been censured as paradoxical, is almost self-evident; for to call up any particular thought supposes it to be already in the mind."—*Elements, &c.* ch. v. sect. 3.

"And binding nature fast in fate,
Left free the human will,"

is inconsistent with a striking passage in the Essay on Man:—

"Who knows but He whose hand the lightning forms,
Who heaves old ocean, and who wings the storms,
Pours fierce ambition in a Cæsar's mind,
Or turns young Ammon loose to scourge mankind?"

But if the foregoing statement of the mode of action of the only voluntary power which we are conscious of possessing over the train of our thoughts is correct, it does not appear possible to deny that ambition or any other passion may be infused into any human mind, without destroying the consciousness, or suspending the action of that voluntary power. And if we reflect on the characteristics of many nations that have appeared on the earth's surface—on the taste and genius of the Greeks, the military spirit of the Romans, the restless energy of the northern nations, the maritime adventure and commercial enterprise of Britain and America—and contrast these with the stationary civilization of China, or the languid, if not retrograde condition of Italy, Spain, or Greece—is it unreasonable to suppose that the designs of Providence as to the progress of the human race are sometimes carried into effect by an occasional infusion into many individuals of our species, of feelings and desires, of the ultimate object of which they have as little perception as animals have of the purposes of their instincts? But to prosecute this speculation farther would be foreign to the object of this paper.

It is still to be remarked, in regard to instincts, that they have been long and justly regarded as among the most important phenomena in nature, in reference to the doctrine of final causes, or the inferences of design, and of the adaptation of means to ends in the arrangement of the universe; and it is important to set in as clear a view as possible the proper use to be made of them in that enquiry.

In fact, the whole plan of the construction of all the different classes of animals bears reference to the instincts with which they are endowed, and would be useless without them. If the fangs and claws of the lion, the jaws and stomachs of the ox or the camel, or the bill and gizzard of the turkey, are admirably adapted for the prehension and subdivision of their respective aliments, as well as their organs of digestion for the assimilation of their food, all these provisions would have been useless, but for the instincts which nature has implanted in these animals, by which their proper nourishment is sought, and the first part of the process of its assimilation is directed.

The mutual adaptation of instincts to structure, of structure to instincts, and of both to the ends of their creation throughout every part and function of an animal, and throughout every grade of the animal creation, has been illustrated by many authors, but perhaps most efficiently by Paley, as the most satisfactory of all the indications of the adaptation of means to ends which the study of the universe presents.

It is indeed so clearly the fact that all the arrangements of the structure of an animal are subordinate to the instincts with which it is endowed, that the whole study of Comparative Anatomy, and the whole classification of animals in so far as it is founded on their varieties of structure, require to be regulated by this consideration. The general principle by which the details of these sciences are held together may be stated to be this:—that while nature has observed a certain unity of plan in the construction, certainly of all the vertebrated, perhaps to a certain degree of all, animals, she has likewise introduced in all parts of the scale just such modifications of that plan as the situation in which each animal is placed, and the office it has to perform, or as the French express it, as the conditions of its existence, demand; and then has implanted in it precisely such instincts as are required to enable it to maintain itself—to turn those provisions to account—to enjoy its allotted portion of sensitive pleasure, and to fulfil the other objects of its creation, under those conditions.

The study of the instincts of animals may be said, therefore, to hold a necessary intermediate place between the study of their structure, and that of the ends or objects of their creation—the structure being subordinate to the instincts, as these are subordinate to the objects of existence; and it is by attending to them that the immense extent and infinite variety of the adaptation of means to ends in the animal creation is perhaps most distinctly perceived.

It is stated by Mr. Whewell, that although the study of Final Causes has been often rejected from the science of Physiology, yet it has been found impossible to keep them separate. "The assumption of final causes in this branch of science is so far from being sterile, that it has had a large share in every discovery which is included in the existing mass of knowledge. The doctrine of the circulation of the blood was clearly and professedly due to the persuasion of a *purpose* in the circulatory apparatus."* But there appears to be some ambiguity in this statement. The term physiology is properly applied to the investigation of the *physical* causes of the phenomena of life—of the powers which are in operation, and the conditions under which they operate, in producing these phenomena. It is true that the different functions of life are dependent on one another in any individual animal; and the science of physiology is most conveniently *taught* by arranging their functions in the order of their dependence, and assigning, therefore, the final cause of each, after explaining the manner in which it is carried on. It is true, also, that the study of the uses to which the different functions are subservient, *i. e.* the study of final causes, has often led to the *detection* of physical causes in this as in other sciences. But

* Hist. of the Inductive Sciences, vol. iii. p. 467.

the final cause cannot be substituted for the physical in physiology any more than in other sciences; and this is what was meant by the assertion of Bacon, that the doctrine of final causes is *sterile*. The object of physiology is to explain, not *why*, but *how*, the various functions of life are carried on. But when the laws of life are even partially ascertained, and their application understood, i. e. when physiological facts are referred to their physical causes, they afford many proofs of design and contrivance, and so furnish a most important addition to the general science of final causes.

The science, relative to living bodies, which may truly be said to have its foundations laid in the study of final causes, is the science of Comparative Anatomy, or of animal morphology; i. e. the exposition of the modifications which the general type of animal structure, and the plan of the functions carried on in that structure, undergo in the different classes of animals, and by means of which the objects of the animal creation are accomplished by the laws of physiology throughout the whole extent of creation. These modifications are determined by the circumstances in which animals are placed on the one hand, and by the purposes which they are to serve in the creation on the other. Every variation of structure has its use, in reference to one or other of these objects, and the branch of natural history which consists in the description and arrangement of these varieties cannot be properly treated otherwise than by keeping their uses constantly in view.

Thus, in regard to the function of digestion in the higher animals, its physiology, properly speaking, consists in reference to the laws of sensation, of instinct, of muscular motion, of secretion, as modified by changes in the condition of the nervous system, of absorption, and of vital affinities and assimilation so far as they are known, by which the reception of aliment, and the changes on the aliment received into the body are effected; in this enquiry our object is *explanation*, and however useful the observation of the purpose served by the organs of digestion may be, in suggesting enquiries or experiments by which the laws of which we are in quest may be made out, it is an interruption, not an assistance, to refer to these purposes, or to the importance of the function in the animal œconomy, as if we thus obtained an explanation of the phenomena: but when these different laws of vital action are explained, their adaptation to the object in view is properly stated as a branch of the doctrine of final causes. And when we trace the modifications which the organs and function of digestion undergo in the different tribes of animals, in the carnivorous, the herbivorous, and the graminivorous,—in the quadruped, the bird, the fish, the insect, the polype, &c., and compare these with the provisions for assimilation and nutrition in vegetables, our object is merely *description*, and the arrangement by which we must be guided in this department of natural history is clearly laid down by attention to the purposes which these modifications are intended to serve, as adapted to the circumstances and to the offices of animals, *i. e.* to their final causes.

As, in this science of morphology, or in tracing the varieties of "metamorphosed symmetry," we do not seek to assign the physical causes of any phenomena, it is no abuse of the doctrine of final causes to assume it as the basis of our arrangements; and that the principle of the unity of plan in the animal creation, without the study of the conditions of existence of the different tribes of animals, by which it is modified, and of the instincts accompanying each modification, is truly *sterile*, was clearly shewn by Cuvier, and has been ably illustrated by Mr. Whewell.*

This observation is strictly applicable to the instincts of animals, considered as an essential element in their physiology. We obtain no *explanation* of the phenomena of instinct by referring to their use, or final cause; but the inferences drawn from the study of instincts, as to the existence and attributes of the Author of the universe, and the insight we thus acquire into the arrangements of the animal creation, are not, on that account, the less certain or the less important.

In order to perceive the extent and importance of these inferences, it is necessary to consider, as has been stated above, not only the mutual adaptation of structure and instincts to each other, but also the adaptation of both, in the case of every animal, first, to the purposes of its own œconomy, and secondly, to the purposes which it is fitted to serve in the general œconomy of nature.

Assuming, as we may safely do, that one great object, if not the most essential object, of all the arrangements of organized beings is to secure the greatest possible amount of sentient enjoyment throughout the world, the varying instincts and powers by which animals provide themselves with food will appear on consideration to be better adapted to the attainment of this end than they could have been on any other plan, consistently with the general laws, that animal enjoyment depends on the maintenance of organized animal structure, and this on the continual appropriation and assimilation of previously organized matter. The different races of animals are widely diffused over the globe by the powers which have been granted them of indefinite reproduction. Those of them which are immediately dependent on vegetables for subsistence are naturally limited by the extent of surface over which vegetation is spread; and when this limit has been attained, the only expedient that can increase the number of animals (and it may be added, one which at the same time varies and multiplies the kinds of animal enjoyments) is to make animals prey on one another, either in the living or dead state. "Such is the command given," says Dr. Roget, "to countless hosts of living beings which people the vast expanse of ocean; to unnumbered tribes of insects which every spot of earth discloses; to the greater number of the feathered race, and also to a

* Ib. p. 472, et seq.

more restricted order of terrestrial animals. To many has the commission been given to ravage and slaughter by open violence; others are taught more insidious, though not less certain arts of destruction; and some appear to be created chiefly for the purpose of quickly clearing the earth of all decomposing animal or vegetable materials (e.g. among the larger beasts of prey, the hyena, the jackall, the crow, and the vulture; among marine animals the crustacea and numerous mollusca, and among the lower orders, innumerable tribes of insects.)

"That a large portion of evil is the direct consequence of this system of extensive warfare, it is in vain to deny. But although our sensibility may revolt at the wide scene of carnage, our more sober judgment should place in the other scale the great preponderating amount of gratification which is the result. We must take into account the vast accession that accrues to the mass of animal enjoyment from the exercise of those powers and faculties which are called forth by this state of constant activity; and when this consideration is combined with that of the immense multiplication of life, which is admissible on this system alone, we shall find ample reason for acknowledging the wisdom and benevolent intentions of the Creator, who, for the sake of a vastly superior good, has permitted the existence of a minor evil."*

This consideration is forcibly stated by Mr. Kirby in relation to one very numerous class of animals. "The object of the creation of the Arachnidans seems to have been to assist in keeping within due bounds the insect population of the globe. The members of this great and interesting class are so given to multiply beyond all bounds, that were it not for the various animals that are directed by the law of their Creator to make them their food, the whole creation, at least the organized part of it, would suffer great injury, if not total destruction, from the myriad forms that would invest the face of universal nature with a living veil of animal and plant devourers. To prevent this sad catastrophe, it was given in charge to the spiders, to set traps every where, and to weave their pensile toils from branch to branch and from tree to tree, and even to dive beneath the waters." "The Scorpions and other Pedipalps are found only in warm climates, where they are often very numerous. Insects multiply beyond conception in such climates, and unless Providence had reinforced his army of insectivorous animals, it would have been impossible to exist in tropical regions. The animals we are speaking of not only destroy all kinds of beetles, grasshoppers, and other insects, but also their larvæ and eggs."†

Without going into further details as to the adaptation of the instincts and powers of animals to their office in the world, we may remark, that there are two peculiarities attending many of the phenomena of Instinct, which make them perhaps more important than any others, as indications of Design in the universe.

† Bridgewater Treatise, vol. ii. p. 302.

1. The evidence of design and of intellect which is drawn from the instinctive actions of animals, is precisely similar to, and comes into strict comparison with, that by which each of us is informed of the mental qualities, and even of the mental existence of every human being except himself. What evidence have we of the existence of reason in any of our fellow-men? Only this, that their actions and their words, which are a set of definite muscular actions, appear obviously to be directed to certain ends, and fitted for the attainment of these ends. Therefore, we say, they indicate design or contrivance, i. e. reason or understanding, in the agents. The adaptation of means to ends is the indication of intellect, to which we yield practical assent every hour of our lives, and it would be a proof of deficiency of our own intellect if we failed to do so. Now, when we survey many of the instincts of animals, especially many of those which are directed to the preservation of their lives or the reproduction of their species,—when we see birds of all kinds building nests for their future progeny, and afterwards vivifying their eggs by incubation,—the salmon ascending rivers to deposit their eggs in contact with the atmosphere,—beavers constructing their houses,—bees or ants piling together their cells and collecting their stores,—the migratory birds repairing to warm climates before winter,—the reptiles excavating their winter retreats,—the squirrel, the dormouse, or the pika, laying up their winter store of provisions,—the snail closing its shell and securing its magazine of air for the return of spring, —the spider spinning its web, and preparing its cell and trap-door,—the ant-lion digging his pitfall,—the fishing-frog spreading his lines,—the camel storing his stomach with water for consumption in the desert,—the pelican filling her pouch with food for her young, and an infinity of other contrivances which the organs of animals enable them to execute, which they do execute day after day and year after year with perfect precision, and without which they could neither maintain their own existence nor perpetuate their species; it is plain that we are contemplating a set of living muscular actions, equally adapted to certain definite ends, and equally efficient for the attainment of those ends, as the words or actions of any human being; and we cannot, without obvious and gross inconsistency, decline to draw from them the same inference that we habitually deduce from the adaptation of means to ends by the muscular actions of human beings. And if we are satisfied by the considerations stated in the beginning of this paper, and, in the case of our own instinctive propensities, by the evidence of our own consciousness, that the reason and intelligence, and anticipation of consequences, which are concerned in, and may be inferred from, these instinctive actions of animals, are not the mental attributes of the animals themselves, we have no resource but to attribute their mental qualities to a superior Being, who gave to the first individual of each species of animals, and perpetuated to each race, its organic structure, its sensations, its muscular

powers, and its instinctive propensities. Either directly or indirectly a Mind, and that not the mind of any living animal, must rule, according to general laws, the instinctive actions of all.

It is true that there have been, in all ages, some resolute sceptics, who do not assent to the proposition that design can be traced from its effects, or that the observed adaptation of means to ends authorizes us to infer the existence of an intelligent agent; but such a sceptic, if he be consistent, must also refuse his assent to the evidence of the existence of any sentient or intelligent being but himself. "How do I know," says Dr. Reid, "that any man of my acquaintance has understanding? I never saw his understanding. I see only certain effects, which my judgment leads me to conclude to be marks and tokens of it. But, says a sceptical philosopher, you can conclude nothing from these, unless past experience has informed you that such tokens are always joined with understanding. Alas, it is impossible I can have this experience. The understanding of another man is no immediate object of sight, nor of any other faculty which God has given me; and unless I can *conclude* its existence from tokens that are visible, I can have no evidence that there is understanding in any man."

In fact, the sceptical reasoner who refuses his assent to the intuitive judgment by which we infer design from its effects, can only be truly and thoroughly consistent if he place no faith in any intuitive truth, or first principle of belief, and therefore disbelieves the suggestions of his own consciousness. "To such a sceptic," says Dr. Reid, "I have nothing to say; but of the semi-sceptics, I should beg to know, why they believe in the existence of their own impressions and ideas. The true reason I believe to be, because they cannot help it; and the same reason will make them believe many other things."*

2. The evidence of design, which we deduce from the instinctive actions of man himself, has this striking peculiarity, that we are actually *conscious* of the propensities which excite them, and at the same time *know* that the purpose or design of these actions is not of our own contrivance. We may be said actually to *feel* the adaptation, designed by Nature, not by ourselves, of the constitution of our minds to the laws of external nature and to the wants of our bodily organization. The very same machinery, consisting of efforts of volition, of actions propagated along nerves, and of contractions of muscles, which we put in motion to accomplish any of those objects which our own intelligence and foresight enable us to understand, we here put in motion in obedience to propensities implanted in us by nature, with as little knowledge of the purpose which it is to serve, and in the first instance with as little knowledge of the pleasure it is to procure, as the heart that beats within us has of the nature and uses of the circulation which it supports. In the performance of every one of these actions, we may truly say that the intelligent mind of man bows to the superior wisdom of the Author of Nature.

The speculations of Darwin on this subject seem intended to weaken the evidence as to the divine existence and attributes drawn from the phenomena of instinct, *first*, by attempting to explain the instinctive movements of young animals on the principle of irregular movements being first produced by uneasy sensations, and then those motions being selected, and voluntarily performed, which are found by experience to appease these sensations or procure pleasure; and *secondly*, by referring to the fact formerly stated, that most instinctive propensities are linked to, and, as he expresses it, "under the conduct of sensations and desires." The first of these assertions is quite inconsistent with what has been observed by others (as already remarked) in regard to the commencement of the instinctive actions in young animals.* As to the second, it is quite plain that the inference, which is drawn from the observed adaptation of means to ends in the phenomena of instinct, does not require that there shall be no mental antecedent exciting the instinctive propensity, but only that the mental antecedent shall not be an anticipation, grounded on reasoning, of the effect which the action will produce. Even if the immediate antecedent of every instinctive effort were a pleasing sensation, it would still be a fact, in the constitution of animals, that certain of their sensations, *and not others*, are naturally followed by certain definite muscular contractions, varying in the different tribes, and each adapted to a determinate end, known neither by experience nor by the reason of the animal exhibiting it; and this is the fact which justifies the conclusion in question. This has been already explained, and is so fully illustrated by Mr. Stewart in the answer, contained in his Life of Dr. Reid, to the criticisms of Darwin, that it is unnecessary to dwell upon it.

But although it is clearly no objection to the evidence of design and benevolence in the Author of Nature, drawn from the phenomena of instinct, that the instinctive propensities are often linked to and excited by certain pleasurable sensations, yet it is a strong indication of the superior power by which they are implanted in the different orders of animals, that when they are in full force, and the object to be accomplished by them is important, they have frequently power to supersede and subvert the motives, by which the ordinary actions of the same animals are regulated, and suspend the ordinary laws of their mental constitution, so as to induce an animal to persevere in actions attended with privation and fatigue and positive suffering. "It ought not to be forgotten," says Paley, "how much the instinct often *costs* the animal that feels it; how much (e. g.) a bird *gives up* by sitting on her nest,—how repugnant it is to her organization, her habits, and her pleasures. An animal formed for liberty

* Essays on Intellectual Powers, p. 621 et seq.

* See Kirby and Spence, Introd. to Entomology, vol. ii, p. 468.

submits to confinement at the very season when every thing invites her abroad; an animal delighting in motion, made for motion, all whose motions are so easy and so free,—hardly a moment at other times at rest,—is for many hours of many days together fixed to her nest as closely as if her limbs were tied down by pins and wires. For my part, I never see a bird in that position, but I recognize an invisible hand, detaining the contented prisoner from her fields and groves, for a purpose, as the event proves, the most worthy of the sacrifice."

INTESTINAL CANAL. See Stomach and Intestinal Canal.

IRRITABILITY; etym. *irrito*, to irritate, stimulate, excite; Syn. *contractility*, Dr. Bostock; the *vis insita*, as distinguished from the *vis nervosa*, of Haller; Germ. *Reizbarkeit;* that peculiar vital power in the muscular fibre by which it *contracts* on being *stimulated*.

The term irritability is certainly not the best which might have been devised to express this vital power, for it only expresses the susceptibility of being irritated; the term contractility is equally inadequate, for it only expresses the result or effect of irritation in peculiar textures; the designation irrito-contractility, if not objectionable by its length, would in my opinion express the fulness of this property in the muscular fibre of animal bodies.

The term irritability was employed by Glisson, and some of its phenomena were not unknown to Harvey, Peyer, Baglivi, and other early physiologists; but it is to Haller that we owe the accurate distinction of this principle from other principles in the animal œconomy, its full development, and its application to physiology. Many were the disputes in his own time as to the degree of his originality and merit in this mattter, and Whytt proved a steady and persevering opponent to his claims; but posterity has done him the justice which his contemporaries pertinaciously withheld; and now whenever there is a doubt as to the meaning or acceptation of the term irritability, that doubt is at once dispelled by adding the epithet Hallerian.

The best *test* of the Hallerian irritability is the electric influence. It is by means of this agent that we detect the presence and the persistence of this vital power. Generally the parts which are originally most irritable preserve their irritability longest; but we are not prepared to say that this is an invariable rule.

As galvanism is the best test of irritability, so a muscle, endowed with a high degree of irritability, becomes in its turn an excellent test of electricity; and it was by the irritability in the muscles of the frog that Galvani first detected that form of electricity which has since borne his name, or that of galvanism.

It is an important question, whether the property of irritability belongs to the pure and isolated muscular fibre, or whether it belongs to this, combined with the nerves—the nervo-muscular fibre. The two textures cannot be separated, the muscular fibres cannot be isolated from the fine fibrillæ of the muscular nerves, and therefore the question cannot be determined by distinct experiment. But many facts, anatomical and analogical, would lead us to attach the term irrito-contractility, at least, to the *compound* texture; the nervous portion receiving the stimulus, the muscular undergoing the contraction.

Why are the muscles which perform involuntary functions so richly endowed with nerves? Some of the disciples of Haller, and especially Behrens, contended, indeed, that the muscular structure of the heart, for example, was not supplied with nerves. The anatomist whom I have just quoted wrote a treatise entitled, "Dissertatio quâ demonstratur Cor Nervis carere," in which he asserted that the cardiac nerves were distributed entirely to the bloodvessels; to this the celebrated Scarpa triumphantly replied in his "Tabulæ Neurologicæ Cardiacorum Nervorum," &c.

Dr. A. P. W. Philip has placed himself at the head of the Hallerian school of the present day: Legallois had asserted that the spinal marrow was the constant and essential source of the action of the heart, which accordingly ceased when the influence of the spinal marrow was removed. But Dr. Philip detected a source of fallacy in Legallois' experiments, and discovered that although to *crush* the spinal marrow suddenly, as in those experiments, suspended the action of the heart, yet that the spinal marrow might be slowly and gradually destroyed, and the action of the heart still remain uninterrupted. Similar experiments were afterwards made with similar results by M. Flourens, and published in his admirable "Recherches sur le Système Nerveux," p. 18. But though Dr. Philip has the merit of detecting the error of Legallois and of establishing the fact that the circulation may continue after the destruction of the spinal marrow, he has totally failed in proving that the action of the heart is independent of the nervous system, and that the irritability of Haller is exclusively a muscular power. It should be remembered that, after the removal of the brain and spinal marrow, the grand centres of the nervous system, the ganglionic or subsidiary nervous centres, remain, and that even after the removal of the heart from the animal body altogether,—in which case I have proved that its power of maintaining the circulation remains,—* there are still probably as many nervous as muscular fibres; and we know that the nerves themselves possess, independently of the nervous centres, the *vis nervosa*, or power of exciting under the influence of stimuli, the muscular fibre to contraction.

I have also positively ascertained that after the destruction of the brain and spinal marrow in the eel, the heart is susceptible of being impressed through the medium of the ganglionic system. "In an eel, in which the brain had been carefully removed, and the

* See my Essay on the Circulation of the Blood, p. 121.

spinal marrow destroyed, the stomach was violently crushed with a hammer. The heart, which previously beat vigorously sixty times in a minute, stopped suddenly and remained motionless for many seconds. It then contracted;—after a long interval it contracted again, and slowly and gradually recovered an action of considerable frequency and vigour."*

Dr. W. C. Henry has added an argument in favour of the theory of neuromyic action of another kind. It is known that certain narcotics, applied to nerves, destroy the *vis nervosa* of that part. Dr. Henry found that "a solution of opium injected into the cavities of the heart, or introduced into the intestine, immediately arrested the actions of these organs."† It seems difficult to imagine that this effect of the narcotic was not produced through the medium of the nervous fibrillæ, the muscular being defended by the internal lining of these organs respectively, in the latter organ, a mucous membrane.

After much consideration given to this subject, we should be disposed to conclude that in the phenomena of muscular action, the stimulus acts upon the nervous fibre, and that the contraction is an effect and the property of the muscular fibre.

If this view be correct, we are necessarily led to consider the *vis insita*, or muscular power, in connection with the *vis nervosa*. This latter power is peculiar to certain parts of the nervous system. It is not possessed by the cerebrum or cerebellum, or by the ganglia; but it exists in the tubercula quadrigemina, the medulla oblongata, the medulla spinalis, and the muscular nerves. The heart itself has recently been observed by Burdach to contract on stimulating the cardiac nerves by galvanism.

We owe the discovery of the distinct limitation of the *vis nervosa*, or, as he terms it, the "excitabilité," to M. Flourens.‡

The following were the supposed *laws* of action of the *vis nervosa* by Haller, Bichât, and Professor Müller, before I began my own researches on this subject:

Haller observes, "Irritato nervo, convulsio in musculo oritur, qui ab eo nervo ramos habet." "Irritato nervo, multis musculis communi, totive artui, omnes ii musculi convelluntur, qui ab eo nervo nervos habent, sub sede irritationis ortos. Denique medulla spinali irritata, omnes artus convelluntur, qui *infra* eam sedem nervos accipiunt; *neque* contra artus, qui *supra* sedem irritationis ponuntur." He concludes, "conditio illa in nervo, quæ motum in musculis ciet, *desuper* advenit, sive a cerebro et medulla spinali, *deorsum*, versus extremos nervorum fines propagatur." And—"ut adpareat *causam motus a trunco nervi in ramos, non a ramis in truncum venire*."§

Bichât observes, "l'influence nerveuse ne se propage que de la partie supérieure à l'inférieure, et jamais en sens inverse. Coupez un nerf en deux, sa partie inférieure irritée fera contracter les muscles subjacens; on a beau exciter l'autre, elle ne détermine aucune contraction dans les muscles supérieurs; de même la moëlle, divisée transversalement et agacée en haut et en bas, ne produit un effet sensible que dans le second sens. Jamais l'influence nerveuse ne remonte pour le mouvement, comme elle le fait pour le sentiment."*

Lastly, Professor Müller observes, "the motor power acts *only* in the direction of the primitive nervous fibres going to muscles, or in the direction of the branches of the nerves; and *never backwards*;" and "*all* nervous fibres act in an isolated manner *from the trunk* of a nerve *to its ultimate branches*."†

It is a singular circumstance, that an established fact in *experimental* research, an established *principle* of muscular action in the animal œconomy, should be without application to physiology. Yet such has been the case. For what is the application of the *vis nervosa* to the explanation of the functions of the animal œconomy?

Before any such application could be made, it was necessary that other modes of action of this power should be ascertained. I have, by a series of experiments, determined *new laws* of action of the *vis nervosa*, and have thus been enabled to make an extensive application of the principle to the functions of life.

The head of a river tortoise being separated between the third and fourth vertebræ:

1. The dorsal portion of the spinal marrow was laid bare to the extent of one inch below the origin of the brachial nerves; the spinal marrow was then excited by means of the probe and by galvanism; both anterior and posterior extremities, with the tail, were moved.

2. A lateral intercostal nerve was then laid bare, and stimulated in the same manner; the same effects were produced as in the former experiment.

These experiments have been repeated many times, and I performed them in the presence of M. Serres and other gentlemen at Paris, in the month of August, 1839. They establish the following *new laws* of action of the *vis nervosa*:—

1. That it does act in the direction *from branch to trunk*;

2. That it is in a *retrograde* direction in the spinal marrow.

The application of these new laws to physiology—the first application of the *vis nervosa* to physiology—is very extensive, co-extensive indeed with all the acts of ingestion and egestion in the animal œconomy. But it does not belong to our present article to treat of this important and extensive subject. We now return to that of irritability in general.

The degree of irritability is not the same in every organ of the body. Haller and Nysten have investigated this subject, and the following are their statements respectively:

Haller observes, "Tenacissima virium insi-

* Op. cit. p. 160.

† Handbuch der Physiologie, i. 656.

tarum intestina sunt, quæ et evulsa pergunt se contrahere et frigida demum; etiam his tenacius cor, si omnia conputaveris, in pullo etiam evidentissime et in frigidis animalibus." *

The observations of Nysten are more extensive, and his inferences were deduced from experiments made upon the human subject immediately after decapitation. They are as follow:

" 1. La contractilité du ventricule aortique était éteinte 49 minutes après la mort;

" 2. L'aorte n'a offert aucun mouvement de contraction;

" 3. Cinquante-six minutes après la mort, la contractilité de l'estomac, des intestins et de la vessie était éteinte; mais ces organes n'ont pu être soumis assez promptement au galvanisme pour connaître la durée rélative de leur force contractile;

" 4. Le ventricule pulmonaire perdit sa contactilité une heure 58 minutes après la mort;

" 5. Deux heures 2 minutes après la mort, le diaphragme ne se contractait plus; les muscles de l'appareil locomoteur perdirent successivement leur contractilité à mesure que le contact de l'air agissait sur eux; mais ceux qui ne furent exposés à l'air que tard, par exemple au bout d'environ 4 heures, ne cessérent de se mouvoir que 4 heures 15 minutes aprés la mort;

" 6. Les oreilletes du cœur, qui étaient exposées à l'air depuis le commencement de l'expérience, ne cessérent de se contracter que 4 heures 40 minutes après la mort." †

But if there be a difference in the irritability of different organs in the same animal, there is a still greater difference in the different animals themselves of the zoological scale. It may be stated in general terms, that the degree of the irritability in the different parts of the animal series, as tested by galvanism, is inversely as the quantity of the respiration; so that in the reptile tribes, in which the respiration is exceedingly low, the irritability of the muscular fibre is such as to afford a delicate test of galvanism; and in birds, in which the respiration is at its maximum, the irritability exists in its lowest degree.

This important subject deserves the fullest development. We shall here, therefore, insert some observations which were read to the Royal Society, and published in the Philosophical Transactions in 1832.

The due actions of life, in any part of the zoological series, appear to depend upon the due ratio between the quantity of atmospheric change induced by the respiration, and the degree of irritability of the heart: if either be unduly augmented, a destructive state of the functions is induced; if either be unduly diminished, the vital functions languish and eventually cease. If the bird possessed the degree of irritability of the reptile tribes, or the latter the quantity of respiration of the former, the animal frame would soon wear out. If, on the contrary, the bird were reduced to the quantity of respiration appropriate to the reptile, or the latter to the degree of irritability which obtains in the former, the functions of life would speedily become extinct. Various deviations from the usual proportion between the respiration and the irritability, however, occur, but there is an immediate tendency to restore that proportion; increased stimulus exhausts or lowers the degree of irritability, whilst diminished stimulus allows of its augmentation. The alternations between activity and sleep afford illustrations of these facts.

Changes in anatomical form in the animal kingdom present other illustrations of the law of the inverse proportion of the respiration and irritability. The egg, the fœtus, the tadpole, the larva, &c. are respectively animals of lower respiration, and of higher irritability, than the same animals in their mature and perfect state. Changes in physiological condition also illustrate the same law. The conditions of lethargy, and of torpor, present examples of lower respiration, and of higher irritability, than the state of activity.

It may be remarked that whilst changes in anatomical form are always from lower to higher conditions of existence, changes in the physiological condition are invariably from higher to lower.

These views are further illustrated by a reference to the quantity of stimulus and the degree of irritability of each of the parts and organs of the animal system. The oxygen of the atmospheric air is the more immediate and essential stimulus of this organ. Taken up in respiration, it is brought into contact with the heart, by means of the blood, which may be considered as the carrier of this stimulus, as it is of temperature and nutriment, to the various parts of the system. As oxygen is the principal stimulus, the heart is the principal organ of irritability, in all the vertebrated animals; if the contact of oxygen be interrupted, all perish in a greater or less period of time.

The extraordinary differences which exist in animals which occupy different stations in the zoological scale, have long excited the attention of naturalists. Nor have the differences which obtain in the various ages and states of its existence, in the same animal, escaped the attention of the physiologist. A similar remark applies to that singular state of existence and of the functions of life, designated hybernation. But it appears to me that a sufficiently comprehensive view has not been taken of the subject, and that many facts, with their multitudinous relations, still require to be determined.

I. *Of the pneumatometer.* — The principal of these facts is that of the quantity of respiration. This is greater in proportion as the animal occupies a higher station in the zoological scale, being, among the vertebrated animals, greatest of all in birds, and lowest in fishes; the mammalia, the reptiles, and the amphibia occupy intermediate stations. The quantity of respiration is also remarkably low in the very young of certain birds which are

* Haller, Primæ Lineæ, 1767, p. 207.

† Recherches de Physiologie, 1811, p. 312.

hatched without feathers, and of certain animals which are born blind; and in hybernation it is almost extinct.

To ascertain the quantity of respiration in any given animal, with extreme minuteness, was a task of great difficulty. It was still more difficult to determine this problem, so as to represent the quantities of respiration in the different kinds, ages, and states of animals, in an accurate series of numbers. The changes induced in a given volume of air made the subject of experiment, by changes in the temperature and pressure of the atmosphere, and by variations in the height of the fluid of a pneumatic trough, which it is so difficult to appreciate minutely; the similar changes induced by the humidity of expired air, and by the heat of the animal itself, were so many and complicated, that it appeared almost impossible to arrive at a precise result. These difficulties, in fine, were such as to lead one of the first chemists of the present day to give up some similar inquiries in despair.

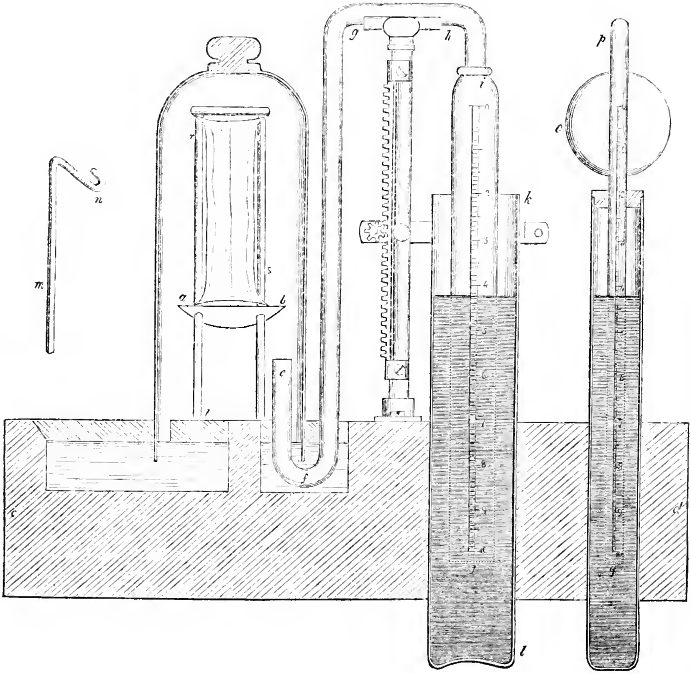
Fortunately I have been enabled to devise an apparatus which reduces this complex problem to the utmost degree of simplicity. I now beg the indulgence of the reader whilst I give a detailed description of its construction and mode of operation.

This apparatus, which I shall designate the *pneumatometer*, consists of a glass jar (*fig.* 1, *a*, *b*,) inverted in a mercurial trough (*c*, *d*,) so grooved and excavated, as accurately to receive the lower rim of the jar and the lowest part of the tube (*e*, *f*, *g*,) and also to admit of the animal which is made the subject of experiment, being withdrawn through the mercury. This jar communicates, by means of the bent tube (*e*, *f*, *g*, *h*,) with the gauge (*i*, *j*,) which is inserted into a larger tube (*k*, *l*,) containing water. A free communication between the jar and the external air is effected and cut off, at any time, by introducing and withdrawing the little bent tube (*m*, *n*,) placing the finger upon the extremity (*m*,) whilst the extremity (*n*) is passed through the mercury.

If the jar be of the capacity of one hundred cubic inches, the gauge is to contain ten, and to be graduated into cubic inches and tenths of a cubic inch; so that each smallest division shall be the thousandth part of the whole contents of the jar.

Attached to the same mercurial trough is placed a little apparatus (*o*, *p*,) termed an *aërometer*, and consisting of a glass ball (*o*,) of the capacity of ten cubic inches, communicating with a tube (*p*, *q*,) bent at its upper part, of the capacity of one cubic inch, di-

Fig. 1.



vided into tenths and hundredths, and inserted into a wider tube containing water, precisely in the manner of the gauge (*i*, *j*.) In order to secure the exact proportion between the capacity of the pneumatometer and that of the aërometer, it is only necessary to add more or less of mercury to the trough.

The whole apparatus is inclosed in a glazed frame so as entirely to obviate the influence of partial currents of air. It is plain that changes in external temperature and pressure will affect both these parts of the apparatus equally; and that the fluids in the gauge (*i*, *j*,) and in the tube (*p*, *q*,) will move pari passu. It is therefore only necessary to compare them, and to take the difference, for the real alteration in the quantity of the gas in the jar.

Previously to noticing this difference, the fluids in the outer and inner tubes are to be brought accurately to the same level, by raising or depressing the outer tube (*k*, *l*,) and the inner one (*p*, *q*.)

In order that the air within the jar and that in the aërometer may be in the same state of humidity, a little water is introduced into the glass ball (*o*) of the latter.

When the animal is to be removed, the fluid in the inner and outer tubes of the gauge are to be brought to a precise level; the animal is then to be withdrawn through the mercury, by a cord attached to the little net or box in which it is secured; a quantity of fluid will immediately rise in the inner tube, (*i*, *j*,) equal to the bulk of the animal; the bent tube (*m*, *n*) is now to be passed through the mercury into the jar so as to effect a communication with the atmospheric air; a portion of air equal to the bulk of the animal rushes into the jar, whilst the fluids in the gauge regain their level.

To avoid the error which would arise from the influence of the temperature of the animal upon the air within the jar of the pneumatometer, the first observation of the degree upon the gauge must be made the instant the experiment is begun, and before the temperature of the animal can have been communicated to it; and the last, so long after the animal has been withdrawn as to allow of its restoration to the temperature of the atmosphere.

In this way all calculations for the varied temperature and pressure of the external air, for augmented humidity and temperature of the air of the pneumatometer, and for the changes in the height of the fluid of the trough, are at once disposed of in a manner the most accurate and simple.

It now remains to determine the quantity of change induced upon the air of the pneumatometer, by the respiration of the animal. Two views may be taken of this change; that of Messrs. Allen and Pepys, that the oxygen which disappears is replaced by a precisely equal bulk of carbonic acid; or that of M. Edwards, that there is generally an excess of the oxygen which disappears over that of the carbonic acid evolved. In either case the quantity of respiration is ascertained by the gauge of the pneumatometer in the following manner. A frame made of glass rods (*r*, *s*) is placed within the jar (*a*, *b*) suspending portions of calico, imbued with a strong solution of pure potassa, and provided with a small dish of wood, so as to prevent the caustic liquid from dropping upon the animal beneath. By this means the carbonic acid is removed as it is evolved, or after the animal is withdrawn. The rise of the fluid in the gauge of the pneumatometer gives the quantity of oxygen which disappears,—whether this be entirely exchanged for carbonic acid, or only partly exchanged for carbonic acid, and partly absorbed, —and denotes the precise quantity of the respiration.

The question itself, of the entire or partial exchange of the oxygen gas which disappears, for carbonic acid gas evolved, is at once determined by employing the same apparatus without the solution of potassa: in the entire exchange, there is no alteration in the bulk of the air of the pneumatometer; in the case of a partial exchange, the alteration in the bulk of the air gives the precise excess of oxygen gas which disappears, over the quantity of carbonic acid evolved.

But this question, and that of the absorption and evolution of nitrogen, with the influence of night and day, of season, &c. are reserved for a future stage of this inquiry.

It is important that the animal should be left for a considerable time in the very situation in which it is to remain during the experiment, before that experiment is begun, and before the jar is placed over it. In this manner the effect of timidity or restlessness is allowed to subside, and prevented from mingling with that of the natural state of the respiration. A bit of cork must also be attached to the mercurial trough, so as to float upon the mercury at *t*, and prevent the disturbing effect of the contact of this fluid with the animal.

It is also well, after having placed the jar in the groove of the mercurial trough, to pour a little water over the mercury exterior to the jar. The apparatus is thus rendered perfectly air-tight, which is not always effected by the mercury alone.

By means of this apparatus we readily and accurately determine the quantity of the respiration of any given animal, in any given circumstances.

II. *Of the measure of the irritability.*—The problem to be next determined is that of the degree of irritability of the muscular fibre, and especially of the heart. The question is beset with scarcely fewer or less difficulties than that of the quantity of respiration, whilst it involves far greater errors and more discrepancy of opinion on the part of physiologists.

Even Baron Cuvier has fallen into these errors. It will be shortly demonstrated that the degree of irritability is, in every instance, inversely as the quantity of respiration. Yet M. Cuvier, in a remarkable paragraph, states the very contrary, and even speaks of that which is the exhauster, as the repairer, of the irritability; whilst, on the other hand, he makes statements which appear to me at variance with this very opinion. In the Anatomie Comparée (tome i. p. 49,) this celebrated writer observes, " Les expériences modernes ont montré qu'un des principaux usages de la respiration est de ranimer la force musculaire, en rendant à la fibre son irritabilité epuisée." See also tome iv. p. 301. Similar observations are made in M. Cuvier's more recent work, the Règne Animal: " C'est de la respiration que les fibres musculaires tirent l'énergie de leur irritabilité," (tome i. p. 57, 2me edit.) " C'est la respiration qui donne au sang sa chaleur, et à la fibre la susceptibilité pour l'irritation nerveuse," (tome ii. p. 1.) On the other hand, speaking of the mollusca, (tome iii. p. 3,) M. Cuvier observes of those animals of low respiration, " L'irritabilité est extrême dans la plupart." The same term is, in fact, used in two distinct senses, in these paragraphs.

No further proof can be necessary of the extreme vagueness and incorrectness of the prevailing notions and expressions of physiologists in regard to this subject. All this will appear still more extraordinary, when the law, that the quantity of respiration and the degree of the irritability are, in fact, inverse throughout all the series, stages, and states of animated being, is clearly established.

It is well known that the irritability of the heart and of the muscular fibre in general is greater in the mammalia than in birds, and in reptiles and amphibia than in the mammalia, whether we judge of it by the force and duration of the beat of the heart, exposed to the stimulus of the atmospheric air, or by the contractions of the other parts of the muscular system. Now this is precisely the order of the quantity of respiration in these animals, as ascertained by the pneumatomer, inverted. It is essential, in accurately determining the question of the irritability of the muscular fibre, to compare animals of the same class inter se; birds and the mammalia, reptiles and amphibia, fishes, the mollusca, &c. must be compared with each other, both generically and specifically. It is especially necessary to compare the warm-blooded, the cold-blooded, the air-breathers, and the water-breathers, in this manner. However the different classes may differ from each other, there are differences in some of the species of the same class, and especially that of fishes, scarcely less remarkable.

Great differences in the duration of the beat of the heart are observed in fœtal, early, and adult states of the higher animals; this duration being greater in the first, and least in the last of these conditions. The order of the quantity of respiration is inverse.

The law of the irritability being inversely as the respiration, obtains even in the two sides of the heart itself, in the higher classes of animals. The beat of the heart removed from the body does not cease at the same time in the wall of all its cavities, or of its two sides: but, as Harvey observes, " primus desinit pulsare sinister ventriculus; deinde ejus auricula; demum dexter ventriculus; ultimo (quod etiam notavit Galenus) reliquis omnibus cessantibus et mortuis, pulsat usque dextra auricula."*

Even in this case the irritability is greatest in the part in which the respiration is least.

It was shown by Hook, in the early days of the Royal Society,† that if, the respiration being suspended, an animal appeared to be dying, the beat of the heart and the signs of life were speedily restored, on performing artificial respiration, or even by forcing air through the trachea, bronchia, and pulmonary air-cells and allowing it to escape through incisions made through the pleura.

It was, in the next place, clearly shown by Goodwyn, in one of the most beautiful specimens of physiological inquiry in any language,‡ that in suspended respiration, it is the left side of the heart which first ceases to contract, the right side still continuing its function for several minutes, until the supply of blood may be supposed to fail.

The facts detailed by Harvey had shown that the left side of the heart was endued with less irritability than the right; the experiment of Hook, that respiration restored the action of the heart, if it had previously ceased; that of Goodwyn, that this cessation and restoration of functions were observed in the left side of the heart. It was obvious, on the other hand, that the respiration belongs, as it were, to the left side of the heart.

It appears plainly deducible from these facts. that in circumstances and structures the most similar, the respiration is accurately inversely as the irritability.

For the sake of a comparison with the hybernating animal, the object of which will be explained hereafter, I thought it right to repeat this experiment.

Before I proceed to detail the result, I may just describe an easy method of performing that part of it which consists of artificial respiration. A quill is firmly fixed in the divided trachea: a small hole is then cut into that part of the quill which is external; Read's syringe is then adapted to the other end of the quill. At each motion of the piston downwards, the lungs are distended; whilst the piston is raised, the air escapes through the opening in the quill, producing expiration. The experiment, therefore, only requires the common action of the syringe.

The experiment itself answered my expectation. During the cessation of respiration, the left ventricle ceased to beat, the right ventricle retaining its function; on renewing its respiration, the left ventricle resumed its beat. It appears from this experiment, that from want of a degree of irritability equal to that of the right ventricle, and its own proper stimulus of arterial blood, the left ventricle ceased its contractions. The function of the right ventricle

* Opera Omnia, Collegio Medicorum Londinensi edita, 1766, p. 28.

† Phil. Trans. vol. ii.

‡ On the Connexion of Life with Respiration: London, 1788, p. 72, 82 note.

must soon cease in consequence, from want of a supply of blood.

These facts prove that arterial blood is the necessary stimulus of the left side of the heart, its irritability being low; but that venous blood is a sufficient stimulus of the right, from its higher irritability: the phenomena plainly flow from the law, that the quantity of respiration and the degree of irritability observe an inverse ratio to each other, and from the facts on which that law is founded. In this double sense, besides that of distinct cavities, the mammalia have, therefore, two hearts; and as the highly aerated blood of the left is the peculiar property of birds and the mammalia, so the highly irritable fibre of the right may be compared to that of the heart of reptiles and the fishes.

Except for the objection to new terms, the left side of the heart might be termed arterio-contractile, and the right veno-contractile; the first being stimulated by arterial, the second by venous blood.

It is quite obvious that the heart will bear a suspended respiration better, the more nearly its irritability approaches to that which may be designated veno-contractile. *The power of bearing a suspended respiration thus becomes a measure of the irritability.* It is expressed, numerically indeed, by the length of time during which the animal can support a suspended respiration; a conclusion of the highest degree of importance in the present inquiry.

Birds die almost instantly on being submerged in water; the mammalia survive about three minutes, the reptiles and the batrachia a much greater length of time.

The unborn fœtus, the young animal born with the foramen ovale open, the reptile, the mollusca, having all a state of the heart approaching to the veno-contractile, bear a long-continued suspension of the respiration, compared with the mature animal of the higher classes.

But the most remarkable fact deducible from this reasoning is the following: if such a case existed as that of the left side of the heart being nearly or absolutely veno-contractile, such an animal would bear the indefinite suspension of respiration; such an animal would not drown though immersed in water. Now there is precisely such a case. It is that of the hybernating animal. It may be shown that in the state of perfect hybernation the respiration is nearly suspended; the blood must, therefore, be venous. See Hybernation. Yet the heart continues to contract, although with a reptile slowness. The left ventricle is, therefore, veno-contractile, and in this sense, in fact, sub-reptile. The case forms a solitary exception to the law pointed out by Harvey, that the left ventricle ceases to contract sooner than the right. If in the hybernating animal the left ventricle does cease to beat sooner than the right, it is only in so slight a degree as to be referred to the greater thickness of its parietes, and the slight degree in which respiration still remains. It is obvious that the foregoing statement must be taken with its due limitations. Venous blood is unfit for the other animal purposes, even though it should stimulate the heart to contraction.

Another mode of determining the degree of irritability, is the application of stimuli, as galvanism. A muscular fibre endued with high irritability, as that of the frog, and the galvanic agency are mutually tests of each other.*

A third criterion and measure of the irritability is afforded by the influence of water at temperatures more or less elevated, in inducing permanent contraction of the muscular fibre.

There are two other properties of animals which depend upon the varied forms of the inverse ratio which exists between the respiration and the irritability. The first is *activity*, the second, *tenacity of life*.

The activity, which, I believe, M. Cuvier has confounded with the irritability, is generally directly proportionate to the respiration, and intimately depends upon the condition of the nervous system resulting from the impression of a highly arterial blood upon its masses, and not upon the degree of irritability of the muscular fibre. It is the pure effect of high stimulus.

To show that M. Cuvier has blended the idea of the irritability of the muscular fibre with that of the activity of the animal, it is only necessary to recur to the passages already quoted from that author, and to adduce the observations with which they are connected. "On vient de voir à quel point les animaux vertébrés se ressemblent entre eux; ils offrent cependant quatre grandes subdivisions ou classes, caractérisées par l'espèce ou la force de leurs mouvements, qui dépendent elles-mêmes de la quantité de leur respiration, attendu que c'est de la respiration que les fibres musculaires tirent l'énergie de leur irritabilite."† "Comme c'est la respiration qui donne au sang sa chaleur, et à la fibre la susceptibilité pour l'irritation nerveuse, les reptiles ont le sang froid, et les forces musculaires moindres en totalité que les quadrupèdes, et à plus forte raison que les oiseaux; aussi n'exercent-ils guère que les mouvements du ramper et du nager; et, quoique plusieurs sautent et courent fort vite en certains moments, leurs habitudes sont généralement paresseuses, leur digestion excessivement lente, leurs sensations obtuses, et dans les pays froids ou tempérés, ils passent presque tous l'hiver en léthargie."‡

It is extraordinary that M. Cuvier should have associated the elevated temperature of the blood with a high irritability of the muscular fibre, when they are uniformly separated in nature, and are, indeed, absolutely incompatible in themselves. The muscular fibre of the frog is so irritable, that it would instantly pass into a state of rigid contraction, if bathed with a fluid of the temperature of the blood of birds.§

* Bostock on Galvanism, pp. 4, 14.

† Le Règne Animal, tome i. pp. 56, 57. 2de edit.

‡ Ibid. tome ii. pp. 1, 2. 2de edit.

§ See an Essay on the Circulation, chap. vii. pp. 180, 181.

The same confusion of ideas on the subject of the activity of the animal and the irritability of the muscular fibre prevails, I believe, amongst our own physiologists; at least, in conversation with two, who may rank amongst the first, I found that they had uniformly considered the respiration and the irritability to be directly, instead of inversely, proportionate to each other.

That singular and interesting property of the lower orders of animals termed *tenacity of life* is, on the other hand, distinctly associated with a high degree of irritability of the muscular fibre. The property may be defined as consisting of the power of sustaining the privation of respiration, the privation of food, various mutilations, divisions, &c. It is greater as we descend in the zoological scale. As activity depends upon the presence and condition of the spino-cerebral masses acted upon by arterial blood, tenacity of life depends upon the diminution or absence of these masses and of this highly arterialized blood, being greatest of all in those animals which approach a mere muscular structure. Almost the sole vital property then remaining is the irritability; and this property does not immediately suffer from division.

It is possible to reduce some of the reptile tribes to a state approaching that of animals still lower in the scale, by removing, by very slow degrees, successive portions of the nervous masses. This is most readily done in animals in which the respiration is already low, and the irritability high, as in the fœtus, in the very young animal, in the reptile, &c., as in the experiments of Legallois,* M. Serres,† myself,‡ &c.

There is, even in animals most tenacious of life, one kind of mutilation—one kind of injury not well borne. As the blood is in its lowest condition of stimulus, it cannot be withdrawn with impunity; even frogs soon perish if their blood be allowed to flow. As the irritability, on the other hand, is high, certain stimuli, as galvanism, slightly elevated temperatures, &c. are speedily fatal. The batrachia are promptly destroyed by immersion in water of a temperature of 108° of Fahr., and some fish and crustacea perish in great numbers under the influence of a thunder-storm. It is a singular fact, that the fish alone, whose food is found amongst animals of a high irritability, should possess an electrical organ for the destruction of its prey.

The application of stimulus has uniformly a tendency to reduce the degree of irritability. The exclusion of all stimuli allows its augmentation. During active exercise the irritability is diminished; during sleep it is proportionally augmented.

We are now led to take another view of this subject of irritability. What is its source? How is it renewed when it has been exhausted? These questions lead us to take up another of great interest, to physicians especially, viz. what is the condition of the muscular irritability in those cases in which the influence of the cerebrum, or of the spinal marrow, or both, is removed respectively? We cannot discuss this subject more clearly than by adducing the following observations, read before the Royal Medico-Chirurgical Society and published in its Transactions, in the year 1839.

The utmost discrepancy of opinion prevails amongst physiologists and medical writers upon this subject. Prochaska, Nysten, and Legallois state, that the irritability of the muscular fibre remains in paralytic limbs; whilst Professor Müller and Dr. Sticker assert the contrary. No attempt has been made to reconcile a contradiction not very honourable to our science. To explain this discrepancy of opinion is one of the objects of this communication.

The authors to whom I have referred, misled by the generic term and idea of paralysis, have not sufficiently distinguished between its different species. Yet it will be found, as we proceed, that this distinction is of the utmost importance in the explanation of the phenomena. In fact, cerebral paralysis, or that which removes the influence of the brain, and spinal paralysis, or that which removes the influence of the spinal marrow, are in totally opposite conditions in reference to the irritability of the muscular fibre in the limbs severally affected; facts equally obvious in experiments and in clinical observations. I must make quotations of some length, for these are necessary to show the present state of the science. I shall then proceed to the detail of my own investigations.

The first distinct notice of this subject which I think it necessary to adduce, is contained in the following extract from the Opera Minora of Prochaska:* "Vis nervosa quæ in nervis a commercio cum cerebro separatis superest, non unâ alterâve musculi contractione, quam irritati cient, exhauritur, sed millenis plane convulsionibus excitandis par est; quod expertus sum in ranâ, cui medullam spinalem in dorso abscidi. Supervixit huic vulneri aliquot diebus; interim irritando medullæ spinalis partem eam, quæ erat infra sectionem, convulsiones in artubus inferioribus excitavi toto tempore, quo supervixit, planè innumeras; neque extremitates inferiores prius mortuæ sunt, quam tota rana; Dein quod vis nervosa in nervis diu persistere possit citra cerebri auxilium probare videntur musculi paralytici, in quorum nervis ob compressionem aliquam præternaturalem totum commercium cum cerebro sublatum est, nihilominus tamen à stimulo electricæ scintillæ longo jam tempore paralytici musculi convelluntur."

More detailed remarks were made by Nysten, and these, from being founded upon very distinct post-mostem experiments on the human subject, have excited more attention. This celebrated physiologist observes, "Chez deux apoplectiques qui avaient succombé au bout de

* Experiences sur le Principe de la Vie.
† Anatomie Comparée du Cerveau, tome ii. p. 224.
‡ Essay on the Circulation, chap. iii. § 1.

* Ed. 1800, p. 84.

quelques jours, l'un à la première attaque et l'autre à la seconde, le galvanisme a déterminé des contractions aussi fortes dans les muscles du côté sain que dans ceux du côté paralysé: les iris des deux côtés sont également contractées." "Cette propriété n'a été complètement anéantie dans les organes musculaires des deux sujets qu'environ 12 heures après la mort; et on n'a observé aucune différence dans les muscles paralysés."*

Legallois makes similar remarks, founded upon experiments made upon animals. He observes, "M. Nysten a montré que dans les paralysies les plus complètes, l'irritabilité se conserve dans les membres paralysés tout aussi bien que dans ceux qui ne le sont pas. J'ai obtenu un résultat semblable d'un expérience que j'ai souvent répétée. Elle consiste à détruire la moëlle lombaire dans un lapin âgé de moins de dix jours; il faut le choisir de cet âge, pour que la circulation ne soit pas arrêtée, et qu'il puisse continuer de vivre. Quoique dans cette expérience, le train de derrière soit frappe de mort, et que ses nerfs ne puissent plus recevoir aucune influence de la moëlle épinière, l'irritabilité s'y conserve, et l'on peut, pendant fort long-temps, faire contracter les cuisses, en irritant les nerfs sciatiques. Il parait donc qu'il se fait dans toute l'étendue des nerfs une sécrétion d'un principe particulier." †

From these quotations from Nysten and Legallois we should be led to the conclusion that the muscles of paralytic limbs, in all cases of hemiplegia and of paraplegia, simply retain their irritability. From another series of observations, made by philosophers equally worthy of our confidence, we should be led to an opposite conclusion.

Some interesting experiments on this point have been recently performed by Professor Müller and Dr. Sticker. The former celebrated physiologist observes,‡ "It was known that, after the division of a nerve, the portion cut off from communication with the brain retains, for a certain time, its excitability; but the question, how far the continuance of the connection with the brain and spinal marrow is necessary for the longer preservation of the irritability of the nerves, and whether the muscles retain their irritability when their nerves no longer communicate with the central parts of the nervous system, could not hitherto be answered with certainty, and had indeed been seldom mooted. Nysten had asserted that the muscles of patients who died a short time after an apoplectic seizure preserved their irratibility, and contracted under the influence of the galvanic stimulus, although the functions of the brain had been paralyzed.

"I had good reasons, however, for believing that, in such cases, the nerves retain their power only for a short time, losing it entirely after a longer interval; for, in experiments on the reproduction of the nervous tissue in a rabbit, I had once observed, that the lower portion of the nervus ischiadicus, which I had divided some months previously, had lost all its excitability; and a similar fact had been before observed by Fowler. I have since performed, in conjunction with Dr. Sticker, new experiments, which have completely confirmed that supposition. To prevent the regeneration of the nerves, and to withdraw more effectually the lower portion from the influence of the brain and spinal cord, a portion of the nerve (the ischiadic) was entirely removed. The experiments were made only on two rabbits and a dog; yet the results were so constant, that they are quite worthy of dependence.

"Eleven weeks after the division of the nerve in the first rabbit, it was laid bare in its course between the biceps and semitendinosus muscles. Contrary to expectation, and to our mortification, the continuity of the nerve was found to be restored. It was divided anew below the cicatrix; and it is remarkable that, although the animal uttered a loud cry, the section excited no contraction of the muscles. The lower portion of the nerve was now exposed to the galvanic stimulus of a single pair of plates, was cut and pulled in every possible way, but not the slightest muscular contraction was excited.

"For the sake of comparison, the nerve of the opposite side was divided, when the animal showed signs of suffering the most severe pain, and violent muscular spasms took place; and, after the division, very slight irritation of the nerve itself, that is to say, of the lower portion of it, or merely of the muscles, excited strong twitchings, even after death.

"Ten weeks after the division of the nerve in the dog, the ends were found to be reunited. The experiment was performed exactly as in the rabbit, and the result, as to the effect on the nerve, was entirely similar: it had lost all its excitability; but the muscles still contracted slightly when stimuli were applied directly to them immediately after death: however, this remaining irritability was gone, while, in the muscles of the opposite leg, the strongest contractions could be excited.

"Five weeks after the nerve had been divided in the second rabbit, we proceeded to examine its state, and were the more interested on account of the short time that had elapsed since its division. The ends were not united; they were somewhat swollen, and connected with the surrounding cellular tissue. In the other instances, the portion of nerve removed measured about four lines only; here its length was eight lines. No contraction of the muscles could be excited by irritating the nerve either mechanically or by a chemical stimulus, caustic potash, or by galvanism; nor by irritating the muscle itself, although the rabbit had plenty of vital power. On the left side the muscles were found irritable, as in the other cases, both before and after death.

* Recherches Physiologiques, 1811, p. 369; compare p. 377 and 419; and Cuvier, Histoire des Sciences Naturelles, tome i. p. 213.

† Œuvres de Legallois, éd. 1824, p. 23 and 24.

‡ See the excellent translation of the "Handbuch der Physiologie," by William Baly, M.D., vol. i., p. 631—633; and compare p. 663, 724, 727, 898, &c. and Grainger on the Spinal Cord, p. 96, 97.

"The foregoing experiments prove, at least, that when the communication of the nerves with the brain is wholly cut off, they gradually lose the power of exciting the muscles to contraction, while the muscles lose their irritability. The result would, however, have been still more decisive if, in place of a single pair of plates, a small galvanic battery had been employed to stimulate the nerves and muscles. That, and that alone, would have enabled us to determine with certainty whether all the power of the muscles, in two of the cases, had been lost. The experiments as they were made, however, prove distinctly enough the necessity of communication with the brain for the preservation of nervous and muscular power. We may from them conclude also that if, after the division of a nerve, the excitability of the lower portion, and the irritability of the muscles are restored, the nerve has itself been completely reproduced; and that this has not been the case if the nerve and muscle do not retain their vital properties."

I may here observe, that an experiment, similar to those of Professor Müller and Dr. Sticker, in which Sir Astley Cooper assisted the late Dr. Haighton, was made in this country many years ago, but never published. The sciatic nerve was divided in a dog. In a few days the lower portion had lost its power of exciting muscular contraction.

These statements appear, then, sufficiently opposed to each other; how shall we explain or reconcile them? Before I proceed to discuss this question, I must beg the attention of the reader to a third series of observations and experiments, in a certain sense at variance with both those which have been detailed.

My own attention was first drawn to this interesting point by the fact, well known to physicians, that if we administer strychnine to patients affected with paralysis, it is frequently the paralytic limbs which first manifest the peculiar influence of this powerful remedy. M. Fouquier has, I believe, too hastily generalized this effect of strychnine on the muscles of paralytic limbs. And how well do I remember the same remark being made by M. Louis, as, in our visit round his wards at La Pitié, we came to a case in point. From that moment I did not cease to revolve the question in my mind, and to devise modes of observation and experiment to solve it. Certainly the conclusion of M. Ségalas d'Etchepare, in regard to it, is any thing but satisfactory. M. Ségalas observes:—

"Ces expériences réunies autorisent donc à conclure que le tétanos produit par la noix vomique a pour condition première de son développement la présence du poison dans le sang, et que les phénomènes qui l'accompagnent sont dus à l'action anormale de ce fluide sur le système nerveux.

"Cette manière de considerer l'action de la noix vomique donne un moyen simple d'expliquer les effets de cette substance chez l'homme, et particulièrement ce fait si remarquable de la contraction des muscles paralysés plus prompte et plus énergique que celle des muscles sains, fait observé d'abord par M. Fouquier,* et constaté depuis par tant de praticiens du premier ordre. Il est facile, en effet, de concevoir que les muscles sains, soumis à la fois à l'empire du cerveau et à l'action du poison, résistent à celle-ci plus que les muscles paralysés, qui, soustraits à l'influence cérébrale, ne sont plus commandés que par le poison."

Upon these observations of M. Ségalas, M. Ollivier remarks—"Mais s'il en est ainsi, comment se rendre raison d'un fait observé depuis long-temps par tous les praticiens, et sur lequel je viens d'appeler l'attention, c'est que la noix vomique cause souvent de violentes douleurs dans les membres paralysés, sans apporter aucun trouble dans les parties saines? Pourquoi cette action spéciale sur les seuls organes paralysés? et, d'un autre côté, la douleur perçue ne prouve-t-elle pas que les parties paralysées ne sont point isolées entièrement du centre nerveux, et qu'ainsi ce ne peut être à cette inconstance qu'on doive attribuer la localisation singulière des effets de la strychnine?" †

It will soon be seen that this view, like a former one, is far too general, far too indiscriminate—that it is not in every case of paralysis, that the strychnine would first display its influence on the paralytic limbs. Meantime, however, I figured to myself the fact of the strychnine acting on the spinal marrow, and diffusing its power equally along the nerves, to the right hand and to the left, to the muscles to which they proceed respectively: and I asked myself the question—Is the difference observed in its ultimate effects on those muscles, the power being obviously the same, owing to a difference in the degree of the irritability of the muscular fibre itself? Is the irritability of that fibre actually augmented? If so, the phenomenon would be explained!

I waited with anxiety for opportunities of submitting this question to the decision of experiment. This I entrusted, in the first instance, to my young friend and intelligent pupil, Mr. Dolman. The result was as I anticipated. A little child, aged two years, was perfectly paralytic of the left arm. The slightest shock of galvanism was directed to be applied which should produce an obvious effect. It was uniformly observed that the paralytic limb was agitated by a degree of galvanic energy which produced no effect on the healthy limb.

A similar patient, with paralysis of one leg, was subjected to the same experiment by my friend and former pupil Mr. W. F. Barlow, and with the same result.

I repeated the trial on several patients affected with hemiplegia, at my own house, uniformly with the same event: the paralytic limbs were always moved by an influence which was lower than that required to affect the healthy limb, or if both limbs were agitated, it was uniformly the paralytic limb which was more shaken than the other.

* Memoire sur l'emploi de la noix vomique dans les paralysies, par M. Fouquier, 1815.

† Traité de la Moëlle Epinière, 1827, p. 841.

I next repeated my observations upon a more extensive scale, at the St. Mary-le-bone and St. Pancras Infirmaries. There were two exceptions to the rule; whilst the numbers in which the phenomena as already described were observed were considerable.

These exceptional cases I shall notice particularly hereafter. I must now remark that these observations seem, even more than those of Prochaska, Nysten, and Legallois, at variance with the experiments of Professor Müller and Dr. Sticker. Before I proceed to discuss this question, I must, however, detail some experiments of my own.

They were made on six frogs. I divided the spinal marrow immediately below the origin of the brachial plexus; and I removed a portion of the ischiatic nerve of the right posterior extremity. I had immediately, or more remotely, the following interesting phenomena.

1st. The anterior extremities alone were moved spontaneously; both posterior extremities remaining entirely motionless, when the animal, placed on its back, made ineffectual efforts to turn on the abdomen.

2d. Although perfectly paralytic in regard to spontaneous motion, the left posterior extremity, that still in connexion with the spinal marrow, moved very energetically when stimulated by pinching the toes with the forceps.

3d. The right posterior extremity, or that of which the ischiatic nerve was divided, was entirely paralytic, both in reference to spontaneous and excited motions.

4th. After the lapse of several weeks, whilst the muscular irritability of the left posterior extremity was gradually augmented, that of the right was gradually diminished, phenomena observed when the animal was placed in water, through which a slight galvanic shock was passed accurately in the direction of the mesial plane.

In this interesting experiment we have, then, first the phenomena of loss of spontaneous motion on removing the influence of the brain, the excited or reflex actions remaining; and the loss of these on removing the influence of the spinal marrow; secondly, in the case of mere cerebral paralysis, we have augmented irritability, and in that of the spinal marrow we have the gradual diminution of this property.

5th. Strychnine being now administered, the anterior extremities and the left posterior extremity, or that still in connexion with the spinal marrow, became affected with tetanus; but the right posterior extremity, or that severed from all nervous connexion with the spinal marrow, remained perfectly flaccid.

6th. Lastly, the difference in the degree of irritability in the muscular fibre of the two limbs was observed when these were entirely separated from the rest of the animal.

In a word, the muscles of the limb paralysed by its separation from both cerebrum and spinal marrow, had lost their irritability; whilst those of the limb separated from its connexion with the cerebrum only, but left in its connexion with the spinal marrow, not only retained their irritability, but probably possessed it in an augmented degree. The next question came to be,—Do these phenomena obtain in the human frame? I visited a patient affected with hemiplegia, including paralysis of the face, and I passed a slight galvanic shock through two pieces of metal, of which one was placed over each cheek. The muscles of the paralytic side were most affected. I repeated the experiment with the same result. I now compared with these, two cases of injury of the facial nerve, passing the galvanic shock in the same manner, through the fibres of the orbicularis: it was now the muscle of the healthy side which was affected by the galvanism, the eyelid of that side being closed, whilst that of the paralytic side gaped as before. I next compared the effect of galvanism in two cases of complete paralysis of the arm, one hemiplegic, the other the result of dislocation of the shoulder. The muscles of the former were more, those of the latter less, irritable than those of the healthy arm respectively, as were also those of the arm of a patient affected with the paralysis induced by lead. Lastly, I compared the cases of paralysis of the lower extremities, one arising after pertussis, and therefore cerebral, the other, I think, from disease within the lumbar vertebræ: in the former there was augmented, in the latter, diminished irritability.

By means of these experiments and observations we are enabled, I believe, to explain all the apparent discrepancies between the statements of former authors, and between each of them and my own.

The observations of Nysten and others determined that the irritability of the muscular fibre still existed in ordinary hemiplegia; but they did not extend far enough to determine the comparative degree of irritability of the paralytic and of the healthy limbs, or the question whether, in the former, the irritability was diminished—the event probably expected—or augmented, a result, I believe, never anticipated.

Prochaska and Nysten and Legallois failed in their experiments, too, by not allowing time for the change in the condition of the irritability of the muscular fibre to take place.

Professor Müller and Dr. Sticker, on the other hand, did not distinguish between paralysis arising from separation from the cerebrum merely, and paralysis arising from separation from the spinal marrow, a distinction of the utmost importance in every point of view, and that which explains the phenomenon under discussion. The term paralysis has been used by all the authors whom I have quoted in too general a sense. This is so true that I may affirm that in one kind of paralysis, that which removes the influence of the cerebrum, and which is therefore paralysis of spontaneous or voluntary motion, there is augmented irritability; whereas in the other, that which severs the influence of the spinal marrow, the irritability is diminished or even annihilated.

We may conclude that in cerebral paralysis the irritability of the muscular fibre becomes augmented from want of the application of the stimulus of volition; in paralysis arising from disease of the spinal marrow and its nerves this irritability is diminished, and at length becomes extinct, from its source being cut off.

We may further deduce, from the facts which have been detailed, that the spinal marrow and not the cerebrum is the special source of the power in the nerves of exciting muscular contraction, and of the irritability of the muscular fibre; that the cerebrum is, on the contrary, the exhauster, through its acts of volition, of the muscular irritability.

As a further deduction from the same facts, we may infer the diagnosis between cerebral and spinal paralysis: mere cerebral paralysis is attended by augmented irritability, whereas spinal paralysis is that which is attended by diminished irritability. This fact will prove useful in many obscure cases.

Having thus cleared up the physiological question, I proceed to the application of the principle to pathology; and I may here observe that there is a whole series of phenomena which admit of explanation by its aid.

And, first, the exception to the rule of augmented muscular irritability in paralytic limbs, is obviously dependent upon its existing in the cases of paralysis from the severed influence of the spinal marrow, as distinguished from those arising from the severed influence of the cerebrum merely.

Secondly, we understand at once why the influence of strychnine is first and most seen in cerebral paralysis in the paralytic limbs.

But there are still some other points which I must bring before the notice of the reader.

The first of these is the influence of emotion in paralytic limbs.

The second is the similar influence of certain acts of respiration; as yawning, sneezing, coughing, &c.

The third, the similar influence of the tonic power.

It must have occurred to us all to observe the influence of surprise or agitation on the arm and hand, and perhaps on the leg, of a patient long affected by hemiplegia, whilst the limbs of the healthy side remained unaffected. In this case the influence of the emotion is, like that of strychnine in the case formerly discussed, exerted equally upon the limbs of both sides; but it is the muscles of the paralytic limbs which are most irritable, most susceptible of the stimulus; it is, therefore, these limbs which are most convulsively affected.

The same phenomenon is not observed in paraplegia, because the influence of the emotion is cut off from the affected limbs.

Case 1.—I was called to a patient a short time ago, affected at that moment with bronchitis. He was forty-three years of age, and at the age of twenty-four had been seized with hemiplegia. Recovering from the immediate danger of the attack, he remained hemiplegic, scarcely regaining the use of the hand and arm at all, and only partially that of the leg.

Whenever this patient is excited by meeting an acquaintance, or in any similar way, he has a little strabismus, and the hand and arm are contracted and convulsed in the most extraordinary manner: whenever he coughs, the leg is thrown involuntarily upwards. The arm is severed, as it were, from volition, but affected by emotion.

Similar facts have been observed in regard to the influence of certain respiratory acts, but especially those of yawning, sneezing, &c.

Dr. Abercrombie details the following interesting case in a note to the late Mr. Shaw.

"I think the following case will be interesting to you and Mr. Bell. I had some time ago under my care, a man affected with hemiplegia of the left side; the palsy complete, without the least attempt at motion, except under the following circumstances: he was very much affected with yawning, and every time he yawned the paralytic arm was raised up, with a firm steady motion, until it was at right angles with his body (as he lay in bed on his back), the fore-arm a little bent inwards, so that his hand was above his forehead at its greatest elevation. The arm was raised steadily during the inspiration, and when the expiration began seemed to drop down by its own weight, with considerable force. He continued liable to the affection for a considerable time, and it ceased gradually as he began to recover the natural motion of the limb."—That is, as I conclude, as the state of augmented irritability was removed by the returning acts of volition.

Not less interesting are the effects of the tonic power. In cases of hemiplegia of long duration, the paralytic limbs, but especially the arms and hands, are drawn into a state of chronic, rigid, contraction. This phenomenon is owing to the principle of tone constantly acting upon muscles now possessing augmented irritability, whilst they are never, or rarely, relaxed by acts of volition.

A similar effect is seen in idiots born with atrophied cerebrum: the influence of volition is wanting; that of the spinal marrow, the source, at once, of the tone and of the irritability of the muscular system, is in constant action, and induces chronic contraction, an effect which must, however, be distinguished from that of spasm, which is excited immediately by some disease of the spinal marrow itself.

I may now resume the subject of the action of strychnine on paralytic limbs. It is obvious that the generalization of M. Fouquier, M. Ségalas, and others, that the strychnine attacks the paralytic rather than the healthy limbs, was too hasty. This is only true in those cases of paralysis in which the muscles still remain in nervous connexion with the spinal marrow; the opposite result is observed in those other cases in which such connection between the muscles and the spinal marrow is intercepted.

I would here make another observation. The arms and hands, generally speaking, are more under the influence of the cerebrum than the lower extremities; and these, on the other hand, are more under the influence of the spinal marrow than the arms and hands. The superior extremities are more and more frequently affected by hemiplegia than the inferior; these are more influenced by tetanus, by strychnine, &c. than the former, a fact which

I have observed, in regard to strychnine, in some cases of hemiplegia. These facts must be borne in mind in making our observations.

Another circumstance must also be noticed. The more perfect the paralysis, generally speaking, the more the irritability of the muscular fibre is augmented. In hemiplegia, the arm is generally at once more paralytic and more irritable than the leg. In chronic cases, however, the irritability becomes impaired, together with the nutrition.

I will now adduce a few cases which, however succinctly detailed, will exemplify and substantiate the preceding observations.

Case 2.—On January the 16th, 1839, I visited a patient who had been seized with hemiplegia nine months before: the arm was perfectly paralytic, the leg less so, the face less so still. On passing the galvanic influence through the arms, the left or paralytic arm was much more affected than the right, and distinctly affected by a force which induced no effect whatever on the right, the tendons starting on each completion of the galvanic circle; the contraction of the muscles of the left side of the face was seen in its effect on the features; and that of the left gastrocnemius, in its effect on the tendo Achillis, when no effect was perceptible on the right side of the face, or in the right leg.

In this patient other and very interesting phenomena were observed:

1st. The arm has, from the beginning, been much more paralytic than the leg or the face:

2d. The influence of strychnine was observed in the paralytic arm and leg only, in the latter more than in the former:

3d. Any sudden noise, or other causes of emotion, affect the paralytic side only—the leg, however, more than the arm:

4th. Yawning and sneezing move the paralytic limbs; the former the arm, the latter the leg, principally:

5th. The act of stretching, and the act of raising the right arm above the head, induce unconscious movements of the left or paralytic arm:

6th. During sleep, the left or paralytic arm and hand are greatly contracted and painfully pressed to the side:

7th. The paralytic arm shrinks from the application of cold, as the sudden contact of a cold hand; an example of the reflex action in hemiplegia:

8th. Lastly, the paralytic hand and arm are constantly in a state of contraction.

I repeated the trials with the galvanic shock, with the same results, on February the 14th.

Case 3.—On January the 15th and 22d, 1839, I passed a slight galvanic shock through the orbicularis of each side of the face, in a patient affected with paralysis of the left facial nerve from exposure to cold, of six weeks' duration. Here the right eyelid was forcibly closed, the left or paralytic eyelid being totally unaffected.

Case 4.—On February the 13th, I passed the galvanic shock through the two orbiculares in a patient whom I visited with Mr. Burford, and in whom the facial nerve was partially paralyzed by the removal of a considerable branch of the nerve, together with a tumour which had formed in its course along the cheek.

The muscle of the paralytic side was unaffected, whilst that of the healthy side closed the eyelids on every application of the galvanic influence.

Case 5.—I have more recently performed the same experiment on a patient affected with paralysis of the facial nerve, from otitis and disease of the temporal bone, with precisely the same result.

Case 6.—On February the 9th, I compared the galvanic influence in two patients at the St. Pancras Infirmary: both were affected with complete muscular paralysis of the arm; the first case was cerebral, being hemiplegia; the second was an injury of the brachial plexus, having resulted from dislocation of the shoulder; the results were what I had anticipated; in the case of hemiplegia, the irritability of the muscles of the paralytic limbs was greater than that of the muscles of the healthy limb; in the case of injured brachial plexus, the opposite state of things was observed, the irritability of the muscles of the paralytic hand and fore-arm being greatly diminished.

Case 7.—On January the 23d, 1839, I passed the galvanic shock through the hands of a patient who had been gradually affected with paralysis of the right, from handling leaden types, as a compositor. Here, again, the paralytic muscles were unaffected by a degree of galvanism, which induced an evident effect on the muscles of the healthy limb.

Cases 8 *and* 9.—On January the 10th, 1839, I galvanized a little boy with paralysis of the left leg; the muscles were more irritable than those of the healthy leg; the affection had followed pertussis, and I concluded that it was cerebral. This conclusion was confirmed by a fact which I learnt afterwards, viz. that in the commencement there was imperfect closure of the eyelids during sleep. On the same day I tried the galvanic influence in a case of partial paraplegia in a little girl, a patient of Mr. Burford; in this case the muscles of the paralytic limbs were less irritable than those of the healthy limbs; I concluded that the disease was seated in the course of the nerves, and probably within the lumbar vertebræ.

Case 10.—It has been suggested to me that the loss of irritability in the cases of spinal paralysis might be owing to the defective nutrition of the muscles. I therefore tried the effect of galvanism in a case of chronic cerebral paralysis, or hemiplegia, with much emaciation of the paralytic muscles. I found these muscles, as before, much more irritable than those of the unaffected limb.

I must repeat, that I am perfectly aware of the sketchy manner in which these notes of cases are given; but I have thought it better to leave the further details for another form of communication.

In the meantime we may conclude, that by the test afforded by the galvanic trough, we are enabled to effect a diagnosis between the cases to which I now allude. Disease of the cerebrum itself,—disease of the dorsal portion of the spinal marrow,—induces cerebral paralysis, hemiplegia, or paraplegia; disease compressing or destroying the facial nerve, or the cauda equina in the lumbar region, induces both cerebral and spinal paralysis. In the former case we shall observe augmented, in the latter diminished irritability of the muscular fibre.

I may now resume the points of this article, and observe,

1st. That the spinal marrow, exclusive of the cerebrum, is the source of the muscular irritability:

2d. That the cerebrum is, in its acts of volition, an exhauster of that irritability:

3d. That in muscles separated from their nervous connexion with the brain we have augmented irritability:

4th. That in muscles separated from their nervous connexion with the spinal marrow we have, on the contrary, diminished irritability:

5th. That the degree of the irritability of the muscular fibre of paralytic limbs, compared with that of the muscles of the healthy limbs, will afford us a source of diagnosis between cerebral and spinal paralysis, and especially between

1. Hemiplegia of the face, and
2. Paralysis of the facial nerve;
3. Hemiplegia of the arm or leg, and
4. Disease of the nerves of these limbs;*
5. Disease of the spinal marrow in the dorsal region, and
6. Disease of the cauda equina in the lumbar region; &c.

6th. That the greater influence of emotion, of certain respiratory acts, of the principle of tone, &c. on the muscles of certain paralytic limbs than on those of healthy limbs, depends on their augmented irritability:

7th. That the same principle explains the greater susceptibility of the muscles in certain cases of paralytic limbs, to the influence of strychnine:

8th. That, in the conclusions of M. Fouquier, Professor Müller, &c., a sufficient distinction was not made between the influence of the cerebrum and of the spinal marrow, which in this, as in so many other respects, have such different properties:

9th. From these and other experiments and observations, I conclude, too, that sleep restores the irritability of the muscular system, by arresting the acts of volition which exhaust or diminish it; muscular efforts, on the other hand, diminish the irritability and induce fatigue.

Before I conclude, I must beg my reader's attention to some experiments of that able physiologist, Dr. J. Reid, of Edinburgh, which appear, at first sight, to be contradictory to those which I have just detailed.

Dr. J. Reid's paper is published in the Fourth Report of the British Association for the Advancement of Science, p. 671. It is as follows:—

"Although physiologists are still divided in opinion as to the question whether nerves furnish a condition necessary to the irritation of muscles, (i. e. whether every stimulus which excites a muscle to contraction acts on it through the intervention of nervous filaments,) they have now very generally abandoned the once prevalent theory, that the irritability of muscles is derived from the brain or spinal cord, i. e. that muscles are continually receiving, through their nerves, from those larger masses of the nervous system, supplies of a certain influence or energy, which enables them to contract; and that some of the statements of Dr. Wilson Philip, in particular, are generally regarded as decisive against this theory.

"Dr. Wilson Philip found by experiment, that the irritability of a muscle of which the nerves were entire, was exhausted by applying a stimulus directly to the muscular fibres (sprinkling salt on them) even more quickly than that of a muscle of which the nerves had been cut, and where all communication with the supposed source of nervous influence or energy had been cut off; and he states generally that a muscle of voluntary motion, if exhausted by stimulation, will recover its irritability by rest, although all its nerves have been divided.

"But in opposition to this statement, and in support of the old theory of nervous influence continually flowing through certain of the nerves into the muscles, it has lately been stated by Mr. J. W. Earle, that when the nerves of the limb of a frog were cut, the skin stripped off, and the muscles irritated by sprinkling salt on their fibres, until they had lost their power of contraction, although they did not lose their power much more quickly than when the nerves were entire, yet *they did not regain their power*, although left undisturbed for five weeks; while the muscles of the limbs of another frog, similarly treated, but of which the nerves were left entire, completely recovered their irritability.

"It occurred as a fundamental objection to the experiment of Mr. Earle, that in the case where the nerves had been divided, the muscles had become inflamed; being found at the end of the five weeks 'softer in their texture than natural, a good deal injected with blood, and with some interstitial deposition of fluid in them;' while in the limb to which the salt had been applied, but of which the nerves were left entire, and where the irritability was recovered, 'although the colour of the muscles was rather darker than natural, their texture remained unchanged, and there was no interstitial deposition of fluid in them.'

"In these circumstances it might evidently be supposed that it was the inflammation and disorganization of the muscles, not the section of the nerves, which prevented the recovery of the irritability in the case where the nerves had been cut; and it became important to have the experiment repeated, with care to avoid such

* In disease of the cervical vertebræ the arms are sometimes paralyzed without paralysis of the legs; this probably arises from compression of the brachial plexus. See Sir B. Brodie's paper in the Medico-chirurgical Transactions, vol. xx. p. 130; the galvanic trough would determine the question.

injury of the limb of the animal as should cause inflammation to succeed the section of the nerves.

"With this view, Dr. Reid performed a number of experiments on frogs, in which the irritability of the muscles of both hind legs was exhausted or greatly diminished by galvanism, after the nerves of one leg had been divided, and the lower part of the limb rendered perfectly insensible and incapable of voluntary motion, (but without stripping off the skin,) while the nerves of the other had been left entire. The state of the muscles of both limbs was examined after some days. The results of these experiments were not uniform; but in several, where every attention to accuracy seems to have been paid, the irritability of the muscles in the palsied limbs appeared to be *restored as perfectly as in others;* contractions being excited in them, in several instances, by the galvanism from four or even two plates, whereas they had formerly been irritated until they were no longer excitable by that from fourteen plates.

"That the muscles which thus recovered their irritability had lost all nervous connexion with the brain or spinal cord was proved, not only by their obvious insensibility, but by afterwards cutting off the heads of the animals and forcing a probe along the spinal canal, which excited forcible contractions in all parts, excepting the palsied limbs.

"Dr. Alison's paper contained the details of several of these experiments; and he stated, in conclusion, that as a *positive* result in such an inquiry must always outweigh a *negative* one, (particularly where a source of fallacy attending the latter can be pointed out,) these experiments appear fully to justify the assertion of Dr. Wilson Philip, that a muscle of voluntary motion may recover its irritability by rest, although all its nerves be divided; and that they afford, perhaps, more direct evidence than any others in support of the doctrine of Haller, now generally admitted in this country, that the property of irritability in muscles is independent of any influence or energy continually flowing from the nervous system, although, like every other endowment of living animals, it is subjected to the control of causes which act primarily on that part of the living frame.

"Dr. Allen Thomson expressed a doubt whether these experiments warranted the conclusion drawn from them, not because he acquiesced in the theory to which they are opposed, nor because he called in question the accuracy of the results described to have been obtained, but because he knew that former experiments had failed in producing such diminution or exhaustion of the irritability of muscles as had been found by Dr. Reid; and conceived it possible that some of the numerous fallacies to which such experiments are liable might not have been sufficiently guarded against.

"The accuracy of Dr. Reid's statement as to the great diminution or apparent exhaustion of the irritability of the muscles under the influence of galvanism, and the subsequent recovery of the power, notwithstanding the division of all their nerves, was satisfactorily established. It is to be remarked, however, that in these experiments, as usual in such cases, the limbs to which the galvanism was applied were kept moist by the same saline solution with which the galvanic trough was charged; and Dr. Thomson has observed, that when they are moistened with pure water, the diminution of the irritability under the excitement by galvanism is much less obvious. Hence he was led to suspect that the apparent loss of power in the muscles under that process might depend, not on the circumstance of repeated excitement, but on a degree, however slight, of injury to their texture by the action of the salt. This inquiry he proposes to prosecute further; but in the meantime it is certain that by the usual process of galvanizing a living muscle moistened by a saline solution, a very great diminution of its irritability may be effected, which may subsequently be regained, notwithstanding the division of all its nerves; and as the fact of its recovery, not the cause of its diminution or exhaustion, is the point on which the inference drawn from these experiments rests, that inference may be held to be sufficiently justified."

The first question is,—what is the nature of that effect produced upon the nervous and muscular system by such agents as those employed in these experiments temporarily to diminish or suspend their powers? The immediate effect of an attack of hemiplegia, the immediate effect of an injury done to the spinal column, by accident, or in an experiment, the immediate effect of galvanism, or other stimuli, applied to the nerves or muscles, is to suspend, for a time, the phenomena of the excito-motory power of the nerves, and of the irritability of the muscles, respectively; which, however, repose renews. What is the nature of these changes? Do they not consist in the sudden reduction and more gradual removal of some *physical* effect, different from the diminution and restoration of a purely *vital* property of these textures, widely different from the slowly induced loss of irritability resulting from the removal of its source, the natural *physical* condition remaining unchanged? At any rate we must agree with Legallois. "Il faut se souvenir que deux faits bien constatés ne peuvent jamais s'exclure l'un l'autre, et que la contradiction qu'on croit y remarquer tient à ce qu'il y a entre eux quelque intermédiaire, quelque point de contact qui nous échappe."*

I must here adduce two experiments of my own, performed and published many years ago.†

"In an eel, in which the brain had been carefully removed, and the spinal marrow destroyed, the stomach was violently crushed with a hammer. The heart, which previously beat vigorously sixty times in a minute, stopped suddenly and remained motionless for many seconds. It then contracted; after a long in-

* Œuvres, Paris, 1824, t. i. p. 21.

† See my Essay on the Circulation of the Blood, 1831, p. 160, 188.

terval it contracted again, and slowly and gradually recovered an action of considerable frequency and vigour."

"A frog was made perfectly insensible by the application of laudanum or alcohol. Its respiration ceased. It did not move on the application of any irritant. The circulation in the web was carefully observed. When it had long continued in the same enfeebled state without change, the thigh was crushed. The circulation in the minute and capillary vessels ceased at once, and never returned. The stomach was now crushed in the same manner. The heart ceased to beat for many seconds. Its beat then returned, but never regained its former force."

In these experiments we have the sudden influence of shock and its gradual subsidence. The experiment is peculiarly interesting in many points of view:—1. it is the only one on record of the effects of shock induced *solely* and *exclusively* through the medium of the ganglionic system; 2. it exemplifies the effect of shock or excessive stimulus on the *heart*, with its gradual though incomplete subsidence.

The connexion of the ganglionic system with the irritability of the visceral muscles,—the heart, the stomach, the intestines, &c. forms the subject of an experimental investigation, in which I am at this moment engaged, and the results of which I purpose to give under the head of *vis nervosa* and *vis insita*. It is probable that the ganglia are to the internal muscular organs what the spinal marrow is to the muscles of the limbs, viz. the power of irritability, &c. This inquiry is founded on a fact first ascertained by myself, that, in spring, we may, by portions at a time with considerable intervals, totally destroy the brain and spinal marrow in the frog, eel, &c. leaving the circulation in the web or the fins and tail.* We have thus isolated the ganglionic from the rest of the nervous system, on which we may therefore proceed to experiment, watching the effect of various agents on the circulation and on the action of the heart, the stomach, the intestines.

We have thus passed in review in its anatomical, physiological, zoological, pathological, and those peculiar relations, the question of the irritability of the muscular fibre. It only remains for us to advert, once more, to the extreme importance of this principle in physiology: all physiology is involved, indeed, in the topic of the nervous system and the vascular system, and the principle of irritability seems, with its various and appropriate stimuli, to be placed between those two.

(Marshall Hall.)

JOINT.—See Articulation, and the articles under the headings of the several joints for both the normal and abnormal anatomy.

KIDNEY.—See Ren.

KNEE-JOINT (normal anatomy of the). Gr. γόνυ; Lat. *genu;* Fr. *genou;* Germ. *Kniegelenk;* Ital. *ginocchio.* The knee-joint, the largest joint in the body, results from the articulation of the os femoris with the tibia below and the patella anteriorly. It admits of extensive motion as a ginglymus, to which is added an arthrodial motion, or a small degree of rotation of the leg and foot, when the joint is partly flexed. The articular surfaces are large and complicated, the ligaments numerous, and the joint chiefly superficial; circumstances necessary to the freedom, stability, and symmetry of the limb, but exposing this important articulation to frequent accident and disease. It is intended here to describe so much of, *a*, the *bones* entering into the formation of this joint, and, *b*, the *cartilages*, *ligaments*, &c., as may be necessary to the elucidation of, *c*, the *mechanical functions.*

(a.) Bones. The shaft of the os femoris, which in the middle of the thigh is triangular, becomes of a four-sided form as it approaches the knee, in consequence of the bifurcation of the *linea aspera.* This rough ridge, which in the middle of the bone forms a prominent posterior angle, divides on entering its inferior third into two diverging lines which terminate at the convex articulating eminences called *condyles;* a flat triangular surface of bone is thus left, where the popliteal vessels lie. The outer line is most strongly marked, and gives origin to the vastus externus and short head of the biceps flexor cruris: the inner line is deficient near the upper part, over which the femoral vessels pass into the ham; it gives attachment below to the vastus internus and adductor magnus. The internal condyle is narrower and more projecting behind than the external; and in relation to the shaft of the bone, it appears to extend further downwards; but the natural oblique position of the os femoris brings the condyles nearly horizontal. The greater width of the pelvis in women gives, cæteris paribus, a greater obliquity to the os femoris than in men. The condyles are separated behind by a deep fossa, out of which the crucial ligaments take their origin; their articulating surfaces are convex both in the transverse and in the antero-posterior directions, until in front they coalesce into one pulley-like surface over which the patella plays in the motions of the joint: this *trochlea* is convex from above downwards, but concave from side to side; its outer half is more prominent than the inner, and extends higher up the corresponding condyle. Above the trochlea there is a flattened or slightly depressed surface, upon which the patella partly rests during complete extension of the joint. The thickness of the os femoris from front to back undergoes little change till the condyles suddenly jut out behind, and the edges of the trochlea rise up in front; but from side to side the shaft of the bone increases in breadth as it approaches the knee, the two postero-lateral surfaces winding gradually round to become antero-lateral, at the same time diverging rapidly to form a smooth slope on the side of each condyle. Towards the posterior part of each of these sloping surfaces, there is an irregular prominence called the *tuberosity,* for the attach-

* Op. cit. p. 136.

ment of the lateral ligaments; below which, on the outer condyle, there is a pit for the origin of the popliteus tendon, and a fossa leading upwards and backwards from it which lodges the tendon when the joint is fully flexed. In the lateral aspect of the bone we best see the peculiar curvature of the articulating surface. In two adult, but rather small, specimens before me the inferior part of the outer condyle is a segment of a circle of fourteen lines radius, while the radius of the posterior portion is only seven lines; similar measurements of the curves of the internal condyle give radii of six and twelve lines respectively: the centre of the smaller circle coincides precisely with the point of attachment of the lateral ligament on each side, and the advantages of this arrangement will appear when we come to consider the functions of the joint. The smooth articulating surface of the trochlea and condyles is, in the recent state, covered with cartilage. Above this surface and in the fossa between the condyles are numerous foramina for the transmission of the nutrient vessels of the bone, the internal structure of which is here made up of minute cancelli. The lower extremity of the os femoris is cartilaginous at birth, becomes ossified from a separate centre, and long continues to form an epiphysis; but it is ultimately joined to the shaft by perfect bony union.

The thigh-bone exposes the largest extent of surface in the knee-joint; that of the *tibia* is the next in size. Its superior extremity is expanded into the same kind of cancellated structure as the os femoris possesses at its lower part; and the width from side to side equals that of the condyles, which rest upon its upper surface. That surface is nearly horizontal, in the erect position of the body; it is irregularly oval, the long axis passing from side to side, and is marked in the centre by a rough prominence or *spine*, in front of which is a depression, and at the back part a notch. On each side of these inequalities there is a smooth articular surface; the inner one the larger, especially from before backwards, and slightly concave; while the outer one is flat round the margin and raised at the inner side by the base of the spine. Viewing the bone in its anterior aspect we observe that below the articular surface it slopes downwards and forwards to the *tubercle* which stands out at the upper part of the shin or *crest* of the tibia; this tubercle gives insertion at its lower part to the strong ligament of the patella, a bursa being interposed between that ligament and its upper smooth portion. Numerous foramina are to be observed round the head of the bone for the purposes of its nutrition. Below the tubercle a section of the tibia shows it much reduced in size and somewhat triangular in shape; the outer side forming, in conjunction with the fibula, a large fossa for the tibialis anticus and other muscles; and the inner, facing also anteriorly, being a portion of that surface of bone which is covered only by skin and periosteum; except at its upper part, where three flat tendons pass upon it to be inserted by the side of the tubercle in the following order; that of the semitendinosus lowest, the gracilis next above, and the sartorius the highest up and most anteriorly. The posterior surface of the tibia at the supposed place of section has advanced considerably forwards, so as to leave a hollow for the popliteus muscle which lies obliquely on this part of the bone. A few lines below the great articulating surface on the head of the tibia there are two things to be noticed on its posterior aspect; at the outer side a small articular surface for the head of the fibula, and at the inner side a shallow pit where the tendon of the semimembranosus is inserted.

The *patella* is a flat disk of bone placed in front of the knee-joint; it equals in width the trochlea of the os femoris to which it is applied, the posterior surface being for that purpose covered with cartilage and divided into two slight cavities by a prominent vertical line; the articular surface is oval from side to side and does not reach to the lower edge of the bone. Anteriorly, the patella is convex, and its horizontal slightly exceeds its vertical measurement, particularly in the female; into its upper edge are inserted the united tendons of the rectus, cruralis, and vasti muscles; into its lower edge the strong ligamentum patellæ which joins it to the tubercle of the tibia; it is covered only by skin, fascia, and some tendinous fibres, to which latter may be attributed the appearance of vertical striæ observable on the bone.

(b.) Cartilages, ligaments, &c.—The whole of the bony surfaces which come into contact with each other or with the interarticular cartilages during the movements of the knee-joint are covered with "cartilages of incrustation" (see Articulation); and the extent of these on the condyles and trochlea of the os femoris, on the head of the tibia and the posterior surface of the patella, is well marked even in the dry bones by their smooth and compact appearance and the total absence of foramina on the parts so covered. Besides these pure cartilages there are two fibro-cartilages of a semilunar form lying upon the head of the tibia, which serve to deepen the articulating surfaces for the reception of the condyles. These *semilunar cartilages, (cartilagines falcatæ,* s. *lunatæ)* as they are named, are thickest at their convex edges which are attached rather loosely to the circumference of the head of the tibia; the concave edges are thin and sharp, and lie unattached between the condyles and the tibia. The two semilunar cartilages differ slightly from each other in the two following points; the inner one is falciform, decreasing in breadth from behind forwards; the greatest width being at the inner and back part, five-eighths of an inch, whilst in front it is hardly more than one quarter of an inch; the anterior and posterior cornua are separated to the distance of an inch, whilst those of the outer semilunar cartilage approach to within three-eighths of an inch of each other; and, besides that the ring is thus more nearly completed, the breadth of the outer one is more uniform, being about three-eighths of an inch throughout the greater part. The thickness of either of them barely exceeds one-

sixth of an inch, at the outer margin or thickest part. They are both composed of concentric fibres, the extremities of which are fixed to the central parts of the head of the tibia, before and behind the crucial ligaments, with whose fibres they intermingle; the anterior extremities are usually joined together by a *transverse ligament*, but this is sometimes wanting.

The *ligamentum patellæ*, of vast importance in the actions of the knee-joint, is yet the most distant from its articular surfaces; it extends, broad and flat, from the lower somewhat pointed portion of the patella to the inferior part of the tubercle of the tibia, being in the adult about two inches in length. It forms a strong inelastic but inflexible bond of union of the patella with the tibia, and may with propriety be looked upon as a continuation of the extensor tendons which are inserted into the upper and lateral margins of the former bone; some fibres indeed pass over its anterior surface, but it is only through this bone and its ligament that the extensor muscles can act upon the leg. The patella is thus seen to be placed in a situation analogous to that of the sesamoid bones, in the tendons which play over bony surfaces, in the hands and feet. The ligament of the patella is covered anteriorly by dense integument, and the fascia of the leg: posteriorly a cushion of fat is interposed between it and the joint at the upper part, while below it is separated from the bone by a bursa, whose situation was pointed out in the description of the tibia. (See *fig.* 111, *b*, vol. i. p. 252.) More closely applied to the joint are the *lateral ligaments*, the *posterior* and the *crucial ligaments;* and portions of the synovial capsule which are described by some anatomists as *alar* and *mucous* ligaments. The lateral ligaments have a vertical direction at each side of the knee, and are placed nearer to the posterior than the anterior boundary of the joint; the upper attachment is in fact to the tuberosity at the centre of the smaller curve which the articular surfaces of the condyles form at their back part. The internal lateral ligament descends from the tuberosity of the internal condyle of the os femoris to beneath the head of the tibia; it is nearly three inches in length, of a flattened form, narrow at its commencement, but enlarging considerably opposite the joint, to the synovial membrane of which as well as to the internal semilunar cartilage it adheres; inferiorly it again contracts in width. Its upper attachment is covered by the fascia lata; below, it is inserted into the shaft of the tibia just beneath the head of the bone, and anterior to its inner angle; and the tendons of the sartorius, gracilis, and semitendinosus cross over it.

The external lateral ligament *(lig. laterale externum)* arises from the tuberosity on the external condyle of the femur, and descends, inclining backwards, partly covered by the tendon of the biceps, to be inserted with it into the head of the fibula; the attachment of its upper extremity is immediately above the origin of the popliteus tendon, which it crosses in its descent, so that this tendon enveloped by its synovial sheath is situated between the ligament and the joint. The deviation of this ligament from the perpendicular direction is perceived most distinctly in the state of extension; when the joint is flexed, the upper attachment of the ligament is brought more into the perpendicular over its fibular attachment, the ligament is relaxed and assumes the perpendicular direction; hence, in the flexed condition of the joint, the external condyle of the femur, or the tibia on it, admits of a more free motion. This ligament is contrasted by its less length and more rounded form with the internal lateral, and is composed like it of shining tendinous fibres; a still shorter set of fibres sometimes passes more posteriorly from the condyle to the head of the fibula, or from the sheath of the popliteus tendon, and has been called the *short external lateral ligament.*

The *posterior ligament (lig. posticum Winslowii)* is a portion of the tendon of the semimembranosus muscle which is given off near its insertion at the posterior and inner margin of the head of the tibia; the portion under consideration forms a flat and dense fascia which passes upwards and outwards to the external condyle, where it becomes adherent to the synovial capsule and mingling with the tendinous origin of the outer head of the gastrocnemius: posterior to it lie the popliteal vessels, and in front of it there is a quantity of firm granulated fat, into which some of its fibres penetrate.

When the posterior ligament and the fat just spoken of are removed, and the joint is extended, the two *crucial ligaments (ligamenta cruciata*)* are brought into view; they may be seen on the anterior aspect by dissecting down the patella from the fore part of the joint, and putting it in a state of flexion; in the former view, the posterior crucial ligament is best seen; in the latter, the anterior: the upper extremities of both are fixed in the fossa between the condyles of the os femoris; their lower extremities are attached to the head of the tibia between the two articular surfaces.

The *anterior crucial ligament* passes from the inner and back part of the *outer* condyle downwards and forwards to the depression in front of the spine of the tibia, where some portion becomes continuous with the anterior extremity of the internal semilunar cartilage. The *posterior* extends from the fore and outer part of the *internal* condyle downwards and backwards to the notch at the posterior margin of the head of the tibia, where it becomes likewise attached to the posterior extremity of the external semilunar cartilage. The crucial ligaments thus derive their name from decussating one another like the strokes of the letter X; the crossing is, however, considerably above their centre: the anterior passes to the outer side of the posterior.

The *synovial capsule*† entirely surrounds the

* [It is useful to bear in mind that these ligaments are called *anterior* and *posterior* with reference to their insertions into the tibia, the one in front of, the other behind, the spine of that bone.—*Ed.*]

† [Weber recommends as a good way of demonstrating the full extent and connexions of the

joint, and there are good reasons for affirming that it is continued in a highly attenuated state over all the interarticular and incrusting cartilages, giving them their smooth and secreting surfaces. (See ARTICULATION.) The remainder of its extent may be traced in the following manner: from the upper edge of the patella it ascends behind the common extensor tendon, and is loosely reflected upon the thigh-bone two or three inches above the trochlea in the extended position of the limb; from each side of the patella it passes backwards in a broad sheet, whose lower margin is attached to the edge of the semilunar cartilage, and thence goes to the tibia, while above it is loosely reflected on to the condyles of the os femoris, at the distance of nearly an inch from their cartilaginous surfaces; from the back part of the condyles these two lateral portions pass into the fossa and join to cover the anterior surface of the crucial ligaments. From the lower edge of the patella the synovial membrane descends to cover the fatty body which is placed in that part of the joint, and it accompanies a small prolongation from that body which frequently passes across the joint to the lowest portion of the trochlea of the os femoris, forming what has been named the mucous ligament; this structure however is not always present. There is some discrepancy in the descriptions of different anatomists as to the *alar* ligaments, which are described as folds at the sides of the patella, and it seems altogether unnecessary to distinguish these lateral portions by name from the other parts of the synovial capsule. They are simply folds of the synovial membrane projecting into the articular cavity, and obviously destined to increase the extent of synovial surface for a greater amount of secretion. This membrane has a dense cellular tissue on its outer surface, by which it is connected firmly to the posterior surface of the extensor tendons and fascia lata. It possesses some degree of elasticity, but its chief power of accommodation to the motions of the joint is derived from its lax connection with surrounding parts.

(*c.*) The *mechanical functions* of this joint, or the movements of which it is capable within certain limits, and the resistance which it opposes to motion beyond those limits, are plainly deducible from a knowledge of the parts of which it is composed. To say that the knee is a hinge-joint with a slight arthrodial or sliding motion, gives a very faint idea of the complex problem which has been solved in its construction: to procure firmness without the aid of bony processes interlocking with one another (as in the ankle and elbow); and yet to combine free power of flexion with impossibility of over-extension; to oppose large surfaces of bone to one another, so as to ensure stability in the erect posture, without making the joint unsightly by its size, are some of the indications most admirably fulfilled.

In the straight or extended position of the leg, the joint is firmly locked so as to admit of no lateral or rotatory motion; the pointing of the toes in and out in this position is effected by moving the hip-joint. The portions of the condyles forming the segments of large circles are, during complete extension, applied to the tibia and form a broad surface of support; the patella is drawn to the upper or deepest part of the trochlea; and the lateral and crucial ligaments, being attached nearer to the posterior than to the anterior surface of the thigh-bone, are together with the posterior ligament put upon the stretch. If the curve of the articular surfaces of the condyles had been uniform, with the lateral and crucial ligaments fixed to the centre of that curve, the posterior ligament only could have acted to restrain the leg from being flexed forwards upon the thigh, and it would be quite insufficient for that purpose: whereas, by the present arrangement, the centre of motion being placed nearer to the posterior surface of the condyles, the lateral and crucial ligaments cooperate with the posterior in opposing a strong check to over-extension. In flexion the joint admits of motion to the extent of about 140 degrees, when it is arrested by the crucial ligaments. During this movement the condyles offer a diminishing surface to the head of the tibia, and the semilunar cartilages have their ends brought closer together, so as to deepen the cavities for their reception: in extension, the reverse takes place, the semilunar cartilages are pressed out from betwixt the bones to their greatest extent. The adjustment of these fibro-cartilages during flexion is effected partly by their elastic power of resuming their shape when pressure is removed, and in some degree by the atmospheric pressure urging these moveable parts between the ends of the bones, to prevent the formation of a vacuity in the joint. During the motions of the knee, the patella undergoes important changes of relative position both with regard to the os femoris and the tibia; it plays over the whole extent of the trochlea, being drawn in extreme extension half its diameter above that pulley, whilst in extreme flexion it has moved through a quarter of a circle and is found at right angles with the os femoris, forming in that situation the surface which comes to the ground in kneeling, and so defends the joint from injury. In relation to the tibia, the patella always keeps the same distance from the tubercle, being joined thereto by the ligamentum patellæ; but as the condyles recede during flexion, the patella follows them; so that a line passing over its anterior surface and that of the tubercle will, if prolonged, reach the point of the great toe, though a similar line in the extended position will fall through the ankle-joint. The necessity for this advancing and receding movement of the patella explains why it is a separate bone instead of forming a process of the tibia, as in the elbow-joint the olecranon forms a part of the ulna; and may also suggest the use of the

synovial membrane of the knee-joint, to distend it by injecting some coagulating fluid, as size, through a hole bored through the centre of the patella.— Mechanik der menschlichen Gehwerkzeuge, p. 195. ED.]

bursa behind its ligament. It has been said above that besides its ginglymoid motion, the knee-joint has a slight arthrodial motion in the bent position: this is strictly a rotation of the tibia on its axis, and the effect is to point the toes more or less to the outer side, rotation inwardly to any great extent being prevented by the crucial ligaments. During this movement of rotation, the inner articulating surface on the head of the tibia advances forwards, while at the same time the outer one recedes; the lateral ligaments allow of this motion, in consequence of their inferior attachments being a good deal below the margin of the joint; and the crucial ligaments permit the successive, though not the simultaneous, advance or recession of the cavities on the head of the tibia. In all positions of the joint the arrangement is such that the attempt to thrust *forwards* the whole head of the tibia is resisted by the *anterior* crucial ligament, whilst the *posterior* prevents it from being driven *backward*.* The mucous ligament and fatty body of the joint change their situation in some degree during its motions and may serve to fill spaces which which would otherwise be left vacant: the idea that they are peculiarly concerned in secreting the synovia has been satisfactorily refuted under "ARTICULATION."

The bursæ in the neighbourhood of the knee-joint are numerous and not unimportant, from the circumstance that some of them often open into the joint itself. In the layers of fascia anterior to the patella, one or more exist, imperfectly formed and very liable to inflame and suppurate. The situations in which the more perfect specimens are found are as follow, viz. behind the ligament of the patella; between the cruralis and fore-part of the os femoris; beneath the internal lateral ligament; at the insertion of the semitendinosus, gracilis, and sartorius; underneath each head of the gemellus; and around the tendons of the semi-membranosus and popliteus respectively; the last-named bursa is continued down some distance between the popliteus and the tibia, and it often communicates below with the superior tibio-fibular articulation, as well as with the knee-joint above. This joint is supplied with blood from the popliteal artery by five different branches, viz. two superior articular, which wind round the lower part of the os femoris; one middle articular which passes through the posterior ligament to the central parts of the joint; and two inferior articular, which take their course round the head of the tibia, and anastomose freely with each other, and with the two upper; the returning veins go to the popliteal.

The comparative anatomy of the knee-joint gives for the most part the same essential structure as we have described in man, though variously modified.

In most animals, when in a standing posture, the knee maintains habitually a state of flexion, and this arrangement conduces much to fleetness and agility of motion. In the elephant, however, the bones of the hind leg form an upright pillar of support, and the knee is extended as in the human subject. The elephant also resembles man in the circumstance of the knee being brought to the ground in kneeling; whereas, in most genera, the true knee is placed much nearer to the body of the animal.

(Alfred Higginson.)

KNEE-JOINT, ABNORMAL CONDITIONS OF.—The abnormal conditions of the knee-joint may be arranged under those which result from disease and accident. The deviations occasionally met with as the consequence of congenital malformation are fortunately rare.

DISEASE.—The abnormal appearances in the knee-joint resulting from disease are those which spring from some specific irritation, such as struma, gout, rheumatism, syphilis, or malignant disease, or from direct violence. Most of these irritations affect all the structures of the

* [The following experiments, which may easily be tried, illustrate the respective offices of the several ligaments.

If the external fibrous investment of the joint be completely removed, taking care that the lateral and crucial ligaments shall be free from injury, the motions of the joint will be in no degree affected; but if the opposite experiment be tried, and the lateral and crucial ligaments be cut, leaving the external fibrous investment uninjured, excepting a small hole made for getting at the ligaments, it will be found that the integrity of the joint is completely destroyed, the bones are but loosely connected to each other, their apposition is destroyed, and they move about indifferently in every direction.

Again, if after dissecting off the external fibrous investment both crucial ligaments be cut, leaving the lateral ligaments as the only bonds of connection between the two bones, it is found that during extension, the fixedness of the joint is unimpaired, but if flexion be made gradually, the bones becomes less in apposition and more moveable, and in the completely bent state of the limb, they become quite loosely connected and may readily be moved from side to side, and the only limit to flexion is from the tibia coming against the femur.

If the lateral ligaments be cut, leaving the crucial uninjured, the bones remain firmly connected when the joint is in the state of complete flexion, and the crucial ligaments still, as in the natural state, oppose any further flexion. In the gradual diminution of the flexion, the junction of the bones becomes less complete, and when the extension has been carried to its full extent, the bones may be separated from each other, and admit of lateral motion; and if the joint be held up so as to allow the tibia to hang from it, the foot will become everted by its own weight, and the two crucial ligaments, instead of their crossed and oblique position, will assume a parallel and vertical direction. These experiments are described by Weber, but there are few anatomists in this country, for many years back, who have not frequently tried them.

The office of the semilunar cartilages is threefold: 1. filling up the empty space which the articular surfaces leave around their point of contact, they distribute the pressure over a greater surface; 2. they serve to distribute the tension of the ligaments in the movements of the joint more uniformly, and thereby to oppose any jarring of the bones against each other; and, thirdly, they deaden the vibrations which in the various movements of the limbs, especially in standing, walking, or running, are propagated along the bones.—Vide Weber, Mechanik, &c. p. 193. ED.]

articulation, and are associated with some form of inflammatory action, either acute or chronic.

Simple acute inflammation of the knee-joint, or acute arthritis genu, may be the result of a contusion, a sprain, or a wound; or there may be no assignable cause. In the latter case it may have been preceded by rheumatic fever, erysipelas, or diffuse inflammation, which had previously engaged distant organs and other structures. The symptoms are usually strongly marked. Considerable pain, which comes on very suddenly, is felt in the knee; the leg in most cases soon becomes flexed and reposes on its outside; and the patient cannot bear the slightest movement to be communicated to the knee-joint. There is considerable increase of temperature in the skin over the affected articulation, together with tension of it from inordinate effusion of synovial fluid into the joint. Although the usual phenomena of redness as an accompaniment of phlogosis may not be observed externally, there can be but little doubt that the capillary vessels pervading the different structures of the interior of the joint are in a state of hyperæmia. The patient has but little sleep, and this is frequently interrupted by unpleasant dreams and painful spasmodic startings of the affected extremity. Œdema of the lower part of the limb now occurs, and in severe cases sometimes extends up the whole leg and thigh, even to the groin. The sympathetic fever may run so high, and the swelling and other local symptoms proceed so rapidly as to deprive the surgeon of any opportunity of proposing or performing amputation to save the patient's life.

The fever in well-marked cases of acute arthritis genu is sometimes symptomatic of the local disease; sometimes it has preceded the local affection, and has been ushered in by a very severe rigour followed by profuse perspiration. Like the disease, the fever will vary in its character. Erysipelas, rheumatic fever, and diffuse inflammation, as has been mentioned, will each occasionally present in their progress examples of the disease of the knee-joint now under consideration, and the accompanying fever will bear the character of the disease with which the inflammatory affection of the joint is associated. The local phenomena presented by an acute arthritis genu do not, however, vary so much, except in degree and severity.

Acute arthritis genu may supervene as a consequence of wounds. Sometimes these wounds are very small. We have known one case in which a puncture made with a fine sewing needle, which was accidentally driven with force into the knee-joint, at the inside of the patella, was the cause of a fatal inflammation of the joint: the point of the needle probably penetrated the bone. The patient, a young woman, was under the care of Mr. Colles many years ago, in Steevens's Hospital. In some instances we have known inflammation of the synovial membrane of the knee to have been the result of a wound of the subcruræal bursa. A countryman had received a transverse wound by the cut of a broadsword just above the patella, and fatal inflammation extended from this bursa, which was opened, to the synovial sac of the knee-joint.

Acute inflammation of the knee-joint has been the result of surgical operations, such, for instance, as that occasionally undertaken for the extraction of moveable bodies which form in the joint and interfere with the due performance of its functions. This operation, we believe, is now very seldom recommended. We have heard and read of many cases in which it has been performed with complete success; on the other hand, we have reason to know that many have died of the inflammation consequent on it, and that others have narrowly escaped with their lives, having ever afterwards an anchylosed knee-joint. It is rather singular, but we believe it to be true, that the inflammation resulting from a valvular opening having been made in the knee-joint has not come on for six or seven days after the moveable cartilage has been extracted; but inflammation being once set up, its course is generally acute and dangerous.

We consider the observations and experience of Mr. Guthrie on the subject of wounds of the knee-joint to be too valuable to be here passed over. "Wounds of the knee-joint," he remarks, "however simple, should always be considered of a dangerous nature, infinitely more so than of the shoulder, the elbow, or the ankle." "I could," he adds, "relate an infinite number of cases on these points, terminating fatally or in amputation, where the injury was severe, or apparently at first but slight, and but few cases where the capsular ligament was opened into by a musket-ball, where the patient has preserved the use of the limb. In every case where the wound was known to be serious, I have invariably been disappointed in the hope of saving the limb." He then adduces the following case as an instance of apparent simple injury that frequently occurs. "This case," he adds, "will shew the danger of all these wounds, and the very great care and attention that are necessary for their cure. Colonel Donellan, of the forty-eighth regiment, was wounded at the battle of Talavera in the knee-joint by a musket-ball, which gave him so little uneasiness, that when a roller had been put on his leg, with some simple dressing, he could scarcely be persuaded to proceed to the rear. At a little distance from the fire of the enemy we talked over the affairs of the moment, when, tossing his leg about on the saddle, he declared he felt no inconvenience from the wound, and would go back, as he saw his corps was very much exposed. I explained to him the dangerous nature of the wounds of the knee-joint, and after he had staid with me a couple of hours, I persuaded him to go into the town. This injury, although at first to all appearance so trifling, and under the best surgical care, caused the death of this officer in a very short time, and proceeded so rapidly as to prevent any relief at last being obtained by amputation."

Some years ago MM. Larrey and Garriques, in France, recommended the amputation of the leg immediately below the tuberosity of the head of the tibia, instead of amputation of the thigh, where it was found impracticable to remove the leg at the ordinary place of election—four inches below the knee-joint. But Larrey made an addition to this operation, namely, the extraction of the head of the fibula. He says, " when the fibula is left short, which is usually the case, it is to be extirpated as useless, and troublesome in the application of the artificial leg, and the skin is to be left as long as possible, to cover the stump." Mr. Guthrie gives Larrey much praise for drawing the attention of the profession to this " great improvement," and adds the weight of his high authority by recommending the removal of the head of the fibula. In alluding to this subject we may appear to be departing from the proper object of this article,—the abnormal appearances presented by the knee-joint; but having known some melancholy examples of acute inflammation of the knee-joint to follow the operation here recommended, we take this opportunity of warning the profession against it. Mr. Guthrie himself says, " it is possible, however, that a case may occur (perhaps one in a thousand) in which the head of the fibula communicates with the general cavity of the knee-joint; in such a case amputation must be done above the knee." Independently of this communication between these two contiguous joints which Mr. Guthrie considers so rare, we have found, by repeated anatomical examinations of the relation existing between the synovial sacs of the knee-joint and that of the superior tibio-fibular articulation, that these two sacs are so close as to have but a thin transparent wall separating them. We consider it, not absolutely, but very nearly impracticable to cut out the head of the fibula in the living subject without making a communication with the posterior and back part of the synovial membrane of the knee-joint, so delicate is the thin transparent membrane which is interposed between the synovial sac of the knee-joint and the little synovial sac which partially envelopes the head of the fibula. Besides, in the living subject it must always prove to be a difficult matter to remove the head of the fibula without interfering with the tendon of the popliteus muscle, as we know the tendon to be enveloped by a synovial production sent down along it, like that which in the shoulder-joint invests the tendon of the biceps. This synovial production is not confined to the tendon of the popliteus, but is also reflected over the groove formed for the reception of this tendon, and must be in danger of being opened in every operation which we can devise for the removal of the head of the fibula; and consequently, although there may be many cases in which it may be advisable to amputate the leg a little below the tubercle of the tibia, *in no case*, in our opinion, should the surgeon attempt to extirpate the head of the fibula. The idea that this small portion of bone, when left, is "useless and troublesome in the application of the artificial leg," may be true, but it is not the less true that in the majority of cases acute arthritis of the knee-joint will be very likely to succeed to this operation; and we feel satisfied that, as soon as these anatomical relations between the synovial sac of the knee-joint and that of the superior tibio-fibular articulation are reflected on, this modern proposal will be rejected.

Among the causes of acute arthritis genu, exposure to cold is very frequently referred to by the patient, and apparently with reason. The knee-joints being less covered by muscular parts than any other of the large articulations, are more subjected to the influences of cold, and on this account are perhaps more generally affected by acute and chronic inflammation than other articulations. It must be admitted, however, that we have met with cases of acute inflammation of the knee-joint for the origin of which we could assign no cause, having come on, as we are accustomed to say, *spontaneously*. Acute arthritis genu sometimes arises as a symptom in the course of different diseases. Thus in diffuse inflammation and in phlebitis it is quite usual to find the joints visited by most severe attacks of inflammation. We have seen examples of acute arthritis supervening suddenly in the course of a severe attack of erysipelas;* and in rheumatic fever and puerperal rheumatism we can see little else than an inflammation of the joints, the nature of the inflammation in these cases, however, being very different.

Although we have here spoken of three different forms of disease, diffuse inflammation, phlebitis, and puerperal rheumatism, we have ourselves long entertained the opinion expressed by Mr. Arnott, Velpeau, Dance, Cruveilhier, our friend Dr. Beatty, and others,† that the three forms of disease in which the acute arthritis we are here treating of occurs, are the same, and that the arthritis in all three is similar, and proceeds from the same common cause, viz. phlebitis and its consequences.

The peculiar form of acute arthritis here adverted to has in almost all cases been found to have been preceded by phlebitis. This may have come on spontaneously, or in consequence of a wound, or of the vessel having been included in a ligature. The form of acute arthritis which has been called puerperal rheumatism has also been found, in many cases, coincident with or preceded by phlebitis of the veins of the uterine system, or of some other veins.‡

We have seen many cases which we considered to be examples of diffuse inflammation in very young subjects, engaging the periosteum of the femur and tibia, and terminating in the complete destruction of the bone, in the short space of three days. Sometimes the periosteum of the femur, for example, formed a complete cylindrical sac containing the detached shaft of the bone.

The symptoms of acute arthritis which occur in the course of a case of diffuse inflammation

* See Dublin Journ. vol. xvii. p. 336, and in this article p. 55.

are usually ushered in by a severe rigor followed by perspiration. The patient is remarkably restless and depressed in mind. If the phlebitis be external, as in that occasionally succeeding to venesection, which has preceded the acute arthritis, the inflammation along the course of the wounded vein will be observed for several days before the attack of arthritis shall come on. Whatever may have been the cause of the inflammation of the joints, the disease does not, as in rheumatic fever, pass successively from joint to joint, completely leaving one joint to visit another. Although varieties may of course be noticed in the local symptoms which this dangerous disease presents, it very constantly happens that a joint once visited by it seldom or never completely recovers its effects. Usually many joints are successively or simultaneously affected, and we very generally discover that one or more of the internal organs is also implicated. Whatever joint is attacked in the course of the disease, it presents the ordinary characters of an acute arthritis. The integuments covering the articulation sometimes wear a pink hue, and always have an elevated temperature. The affected limb is powerless. The patient complains of very considerable pain, more particularly, as it appears to us, in puerperal arthritis than in the affections of the joints which attend on the ordinary forms of diffuse inflammation. The swelling, when first examined, is soft and fluctuating. After a time the effusion of synovial fluid and pus increases, giving rise to the distension of the synovial sac. If at this advanced period we carefully examine the parts immediately surrounding the inflamed joint, we can discover that the integuments and subjacent parts feel somewhat indurated and œdematous, reminding us of the hardened basis which we find circumscribing an abscess. It is probable that this condition of the surrounding parts arises from diffuse inflammation and the infiltration of its digested purulent matter. The arthritis in these cases is seldom the cause of death; either some internal vital organ becomes violently inflamed by which the death of the patient is accelerated, or abscesses form in the subcutaneous or intermuscular cellular membrane in various parts of the body, which, although more slowly, as certainly lead to a fatal issue, for when the evacuation of the pus takes place, the quantity of matter which is discharged and continues to be secreted is so excessive as greatly to reduce the patient's strength, and the exhaustion from this source and from the diarrhœa which usually attends are sufficient to prostrate the powers of the youngest and strongest individuals. Most writers indeed have observed that in the majority of cases the subjects of this disease had been in a bad state of health at the time the exciting cause came into action,—a cachectic condition produced by over-exertion of mind or body, and that from these circumstances the susceptibility or predisposition to this disease most probably arose.* These observations are, we believe, fully borne out by experience, and it may not perhaps be uninteresting to adduce some remarks published by an author nearly forty years ago, which prove that he was practically acquainted with the complaint denominated by the moderns puerperal rheumatism or puerperal arthritis, and that he took a similar view of the predisposing causes of this disease. Mr. Russell in his work on the knee-joint, in treating of acute cases of what he calls white swelling, says: "in those cases which proceed most rapidly, the disease will reach its acmé in the course of a few weeks." The very rapid and acute cases seem to be connected with some state of great relaxation and weakness. He adds, "the most remarkable instances of this variety which have fallen under my observation, have occurred in the cases of women in childbed." In the Richmond Hospital (Dublin) we had had many cases of this form of acute arthritis, from which we select the two following as serving to illustrate some of the foregoing observations. Both these individuals were in a delicate state of health when the disease attacked them, and the swelling of the knee-joints and other articulations formed a very small part of their diseases.

Andrew Turner, 28 years of age, was admitted into the Richmond Hospital on the 7th of May, 1836. He had much abused his health and constitution. Five days after having been bled in the right arm to relieve the consequences of a severe beating, a superficial diffused redness appeared on the skin of the forearm; the venesection wound was swelled and inflamed; a severe rigor occurred, followed by profuse perspiration and fever; erratic erysipelas characterized by a faint red mottling of the skin in patches appeared; a blush of inflammation in the form of a patch showed itself on the shoulder, but not continuous with that on the fore-arm; a pink patch next appeared over the right knee, then on the left arm, and afterwards on the left lower extremity; and while this disease invaded the body part after part, those once occupied remained engaged as before. On the 15th May, the ninth day from his admission, there was observed effusion into the right knee and into the bursa which is subjacent to the cruræus muscle. Although considerable, this effusion escaped the patient's attention; he complained of no pain, and to our enquiries always replied that he was going on "gaily." On the 18th the left knee-joint was tumefied, but not to the same extent as the right. He died on the 26th, his death being preceded by the ordinary symptoms of pneumonia, pleuritis, &c. On the post-mortem examination the anatomical appearances of pneumonia, pleuritis, and bronchitis were seen; there was also effusion into the cavities of the pericardium and peritoneum. In the right knee-joint and subcutaneous bursa, which freely communicated with it, there was a large quantity of yellowish green fluid, which seemed to be formed of the mixture of purulent matter with the synovial fluid: flakes of lymph floated in it. The synovial lining of the subcruræus bursa was very red, as was also that of the joint itself. The synovial membrane was elevated above the level

* See Dr. Beatty, Dublin Journal, &c.

of the cartilages by subsynovial infiltration. The ligamentum mucosum, as it is called, was very vascular. The capillary system of the semilunar cartilages was injected with minute red vessels. The left knee-joint, which had been but lately attacked, contained an inordinate quantity of synovial fluid, of a greenish-yellow hue, and of a thicker consistence and a deeper colour than natural. The synovial membrane was pale, and there was no infiltration in its subsynovial structure. The vein in which venesection had been performed was contracted in the neighbourhood of the wound, and lymph adhered to its lining membrane. Above the right elbow-joint and internal to the course of the vein, there was a small collection of matter between the skin and fascia.

Susan Brett, æt. 24, was brought into the Richmond hospital on 26th February in great distress and pain. On the 14th February she was suddenly seized with convulsions, being seven months pregnant. She was bled in the right arm and her head shaved. Two days after the operation the arm became very painful and swollen. The pain increased, and on the 21st labour-pains came on and continued during the day. In the evening she was again attacked with convulsions, and blood was drawn from the left arm. The child (her first) was not expelled until early the next morning; the evening of the same day she had a severe rigour, which lasted half an hour, and was succeeded by profuse perspiration; this soon went off, but she remained cold and chilly for the remainder of the night. On the following morning (23d) she was seized with what she called severe rheumatic pains in her hips and right shoulder, which left her "all sore" and completely powerless. On the 24th the pain in the right shoulder-joint became most intense, and a severe stitch seized her in the same side, which prevented her drawing her breath. The pain in the arm also was now very severe, extending upwards from where venesection was originally performed. The wound was found not yet healed.

When brought to the hospital, the fifth day from her lying-in, she was in great distress and pain. Her pulse was 140, with some fulness, but still compressible. She preferred lying on her right side bent forwards, with her knees drawn up. Her respirations were fifty-two in a minute, and greatly oppressed. At each effort of inspiration the alæ nasi were much dilated. Her countenance was anxious, and there was a bright circumscribed flush on each malar eminence. For the last week she has raved constantly at night, and has been more ill at certain hours of the day, very early in the morning, and again at half-past five, P.M. At the latter hour she was generally found perspiring copiously. Her bowels were too free. She complained of pain chiefly in the right shoulder and the lower part of the back; also in both her knees and metacarpal joint of the index-finger of the left hand. She also complained of her left hip. The right arm was swollen but not discoloured, œdematous, and pitting on pressure. The original wound made for venesection was gaping, with unhealthy everted edges; no matter exuded from it. She kept the arm in the flexed position; to herself it felt quite powerless, and when the least movement was communicated to it, she suffered great torment. There was a hard line up the arm corresponding to the course of the basilic vein, and when even the slightest pressure was made in this line, she suffered pain. Immediately above the elbow-joint the skin was hard; the subcutaneous cellular structure seemed more or less œdematous as if infiltrated with fluid; the skin and subjacent parts seemed to be matted together and somewhat œdematous, and pressure here also gave the patient much uneasiness. There was a suffused pink blush on the skin covering the metacarpal joint of the index finger; the joint was much swollen, and she complained of much pain in it. Her principal suffering was from dyspnœa. An examination of the chest by auscultation and percussion furnished all the evidence of extreme bronchitis in both lungs, pleuritis with incipient pneumonia: it was also inferred that effusion had taken place into the right side of the thorax.

On the 28th February some of those deceitful appearances of amendment not unusual in the course of acute disease discovered themselves. It was reported that she had passed a better night; her pulse fell to 128; her respiration was reduced to forty in the minute; but in the evening a pain, which she referred to the situation of the diaphragm, came on with great severity. Her cough was troublesome and in paroxysms; she expressed great anxiety about herself, inquiring whether there were any hopes for her, and complained of pain in her left elbow, where, however, there was no swelling. The original wound made in the right arm for the first venesection was still open, but there was no inflammation about it. The wounds made in the left arm for two subsequent bleedings healed perfectly. She now had pain in all her joints, particularly in the metacarpal joint of the index finger of the left hand. The shoulder-joints were swelled, and she could not bear the slightest movement of them. Her knees were very painful, chiefly the left, which was greatly swollen, but its integuments were not discoloured. Diarrhœa was very troublesome.

On the 2d of March profuse perspiration broke out over the whole body, and œdema of the feet came on. The next morning her pulse was 128; respiration was jerking and very much hurried; and her countenance betrayed great internal distress. She had raved all night. There was complete orthopnœa, and the swelling of the knees increased. She died at four o'clock.

On an examination of the body twenty-two hours after death, the shoulder-joints were found to contain a viscid greenish imperfectly formed pus. Matter of the same appearance, but less viscid, was met with on cutting down to the right shoulder-joint among the muscles external to it. The cartilages in both these articulations had lost their colour and seemed thinner than natural, but were not ulcerated. The elbow-joints were in a normal condition. The joint of the index finger contained a thin greyish coloured matter, which was not confined to the joint, being also found in the muscles external to it. The cartilages on the head of the metacarpal bone and corresponding surface of the index finger were much ulcerated and partially removed. The knee-joints contained a large quantity of a viscid greenish matter like lime-water and oil. Behind the right knee-joint, and extending down to the gastrocnemii muscles, matter of somewhat a similar character, except that no synovial fluid was mixed with it, occupied the interstices of the muscles and the cellular tissue of the lower part of the poplitœal region. The hip-joint did not contain any matter.

The basilic vein of the right arm was plugged up with a dense coagulum, which closely adhered to its internal tunic, and was not easily separable from it. There was no pus in the vein; its exterior presented an unusual red colour.

On opening the cavity of the chest a quantity of serum escaped. There was a great quantity of a very yellow lymph effused on the surface of the pleura of both lungs, principally the right. In many places it was very thick, rough, and consistent. On the diaphragm and in the right side of the chest the lymph was soft, of a greenish colour, being in shreds easily removed, and leaving the subjacent membrane highly vascular. There were also evidences of interlobular pleuritis having existed: all division into lobes had been effaced. The lungs presented specimens of pneumonia in its three stages. A very small portion of the apex of the left lung alone seemed healthy, but even here the bronchial membrane was engaged and presented evidences of bronchitis having existed. In the substance of the lungs there were also found small abscesses presenting near their surface like little gangrenous abscesses surrounded by ecchymosed red spots; these contained some grumous dark-coloured fluid, which, however, was inodorous. In others was found an ill-digested purulent matter; and leading to one of these disorganized portions of the right lung near its apex, the minute veins on very careful dissection were found thickened, with yellow parietes; and many of those present at the examination satisfied themselves that these minute veins contained purulent matter. The heart and pericardium were natural. The most careful examination could discover nothing abnormal in the uterus. The large intestines throughout presented numerous ulcerations on their mucous surface; the neighbourhood of the ileo-cœcal valve being most beset by them. The mucous membrane was in a state of hyperæmia.

The prognosis in cases of acute arthritis genu is in general very unfavourable except when the disease accompanies what has been usually termed rheumatic fever. In this case the synovial system of all the articulations is visited in succession, until the inflammatory disease exhausts itself as it were in three or four weeks, often leaving no trace behind. It is, however, well known to medical men that in the course of these fevers fatal metastasis may occur from the synovial membrane of the knee or other joint to the pericardium or peritoneum.* In some few cases, after the general rheumatic fever and acute specific arthritis had subsided, we have known the chronic rheumatism, or nodosity of the joints, to set in, remaining permanently to interrupt the patient's health. Not long ago there was a young woman in the Richmond Hospital, under the care of Dr. Hutton, having acute arthritis of the right knee-joint, which had remained after a severe attack of general rheumatic fever. All the joints in succession had been visited by inflammation. The fever, with its debilitating accompaniments, profuse perspirations, &c. subsided, but the local symptoms of acute arthritis of the right knee-joint continued, and increased even to suppuration, nor did amputation of the limb save the patient's life. These unfavourable results of acute arthritis, of the rheumatic form, may be considered as exceptions. In general the form of inflammation of the joints, commonly called rheumatic fever, terminates favourably; on the contrary, in cases where the knee-joints and other articulations are engaged during an attack of diffuse inflammation, puerperal arthritis, or phlebitis, the prognosis is most unfavourable, the disease in all these cases being generally fatal whether the joints be implicated or not.

Anatomical characters of the acute arthritis of the knee.—On examining the interior of a knee-joint which had recently been the seat of acute inflammation, we find that the synovial fluid has accumulated in the cavity of the joint, and that it is mixed with purulent matter; when this is removed, we perceive that the synovial sac has been widened and enlarged, and that the subsynovial tissue is much infiltrated, causing the synovial membrane to be raised up above the level of the articular cartilages. We have seen the synovial membrane or subsynovial tissue as red as the conjunctiva oculi in acute purulent ophthalmia. In these cases the articular cartilages lose much of their natural white silvery lustre, become yellowish, and are found softened at their edges or circumference, where the elevated and inflamed synovial membrane is in contact with them. We have found the cartilage of the patella softened and partially detached from the bone, even in very recent cases. In cutting down to the joint we have noticed an alteration in the natural colour of the muscles; and outside the synovial sac we often encounter abscesses containing true pus. Generally speaking this sac is of an intensely red colour, and covered here and there with a green but not very consistent layer of organizable lymph. Some fragments of thinned shreds of exfoliated articular cartilage, with serrated edges, hang into the cavity of the joint, and some portions are altogether free,

* See Dublin Hosp. Rep. vol. ii. p. 321. vol. iv. p. 365.

and float about loose in the interior. We have found the minute capillary vessels of the cartilages faintly traced in red lines, and have also discovered that these vessels admit the colouring matter of our injections. The vascularity of the cartilages under the influence of acute inflammation seems to be fully proved. We have it on the authority of Sir B. Brodie that he had been able to detect with the naked eye vessels in articular cartilage filled by blood; and it is fresh in the recollection of the profession that Mr. Liston has lately laid before the Medico-Chirurgical Society important observations on this subject.—The periosteum of the bones in the immediate vicinity of the knee is usually found to be of a red colour, thicker than natural, and easily detached from the bone; the bones themselves occasionally present a reddish or pink hue externally, and a section of them shews, by its bright red colour, an increase in the number or size of the capillary vessels, admitting red blood, which pervade their medullary membrane and cancellated structure.

Example of acute arthritis genu.—Michael Roche, twenty-seven years of age, was admitted into the Richmond Hospital in April 1832. He had an emaciated appearance, a dry tongue, and some fever. He complained of severe pain in the left knee, which completely interrupted sleep, and of frequent spasmodic startings of the limb. The limb was so much swollen that measurement of it showed an increase of six inches in its circumference over the sound one. The superficial veins were dilated, the patella was thrown much forwards, and the leg and foot were œdematous; the integuments were red and thinned, and a fluctuation of matter in the joint was very evident. He stated this violent attack to be of five weeks' duration, having commenced with a very severe rigor, and attributed it to his having lain for some hours on wet grass. Three years previously he had had an attack of acute inflammation of the knee, which, however, quickly subsided, but leaving a stiffness of the joint. An opening was made with a lancet into the part of the knee-joint which was red and thinned, and eight ounces of purulent matter were let out, but no relief was afforded. Some superficial inflammation was observed, in the course of the lymphatics to the groin, from the wound, as also swelling of the inguinal glands. The spasmodic startings of the limb became more urgent, and the œdema increased. On the 17th of April Dr. M'Dowel amputated the limb. The incision passed through a sinus which he thought it necessary to dissect out. The muscles did not retract. On the following day the report from the man was that he rested well at night. But on the fourth day after the operation his countenance was flushed, his pulse feeble—96, and he complained much of the pain of the stump. On the 22d of April, the fifth day after the amputation, he had a rigor followed by a hot and sweating stage: his pulse amounted to 144. For some days subsequently he had frequent rigors. The stump was not doing well; the muscles were shrinking away daily and leaving the bone uncovered. The edges of the wound had a sloughy appearance, and towards the end of the month he was attacked with diarrhœa which in a few days proved fatal.

On an examination of the knee-joint all the structures entering into its composition exhibited evidence of their having been the seat of recent high inflammatory action. The bones and synovial membrane presented a very great degree of vascularity and redness; purulent matter and flakes of lymph were contained in the interior of the joint; a fragment of one of the semilunar cartilages alone remained, and the articular cartilages were in many places removed altogether; in other situations these latter were thinned very much, and in one or two places a number of minute perforations were seen in the articular cartilage investing the lower end of the outer condyle of the femur. The minute vessels of the joint were rendered evident by a previous injection of fluid size coloured by vermillion. The synovial membrane was much thickened and raised above the level of the cartilages; it presented a red pulpy appearance, and productions from it passed from the side of the femoral condyles and were loosely folded over the articular cartilages; and wherever this loose membrane was in contact with the articular cartilages, these seemed to have been absorbed. Depressions in the cartilages exactly corresponded in form with this vascular membrane, which was lodged in these superficial depressions. The articular cartilages were thinned, and when elevated from the bone a red pulpy membrane, very similar in appearance to the free surface which the synovial membrane presented, was seen. The minute pores and perforations in the articular cartilages already noticed were evidently formed by the action of a pulpy membrane subjacent to them, and causing their absorption, evidently in the same manner, it appears to us, as we find an exfoliation from a flat bone of the cranium to be perforated by the absorbing powers of the granulations proceeding from the bone beneath it. In examining this preparation, and reflecting on the history of the case, it would appear that when the limb was amputated, the complete destruction of the articular cartilage was in progress. On the free surface towards the cavity of the joint, the cartilage was evidently absorbed by the villous productions from the inflamed synovial membrane; on the osseous surface the cartilage was acted upon by a pulpy membrane, which existed here also, and it was this membrane which was produced from the bone and caused the number of minute perforations already alluded to, having partially removed the articular cartilage.* The bones were in a condition of hyperæmia. This newly formed membrane seems to be endowed with a power of absorbing, by its villi, the cartilage with which it comes in contact; for we must agree with Mr. Key that these vascular fimbriæ or tufts are often buried into excavations in the

* The preparation is preserved in the museum of the Richmond Hospital.

cartilage, and the convexity of the villous membrane seems sunk into foveæ formed in the cartilage, so as to leave no doubt of the vital mechanism, if we can so say, of the process, which seems quite analogous to the absorption of the sequestrum of a cylindrical bone, or the exfoliating piece of a flat bone. The writer presented to the Pathological Society of Dublin a recent specimen and a drawing of the knee-joint of a man aged seventy, William Walsh, who died the day previously (13th Dec. 1839) in the House of Industry, of an attack of acute arthritis genu which had supervened on a chronic disease of the joint of long standing. The synovial sac of the joint had been much distended and was more capacious than usual. It was greatly thickened, and presented on its internal surface an intense scarlet colour. Extensive deposits of a yellowish green lymph were noticed over the entire of the synovial sac: the strong contrast in colour between the green lymph and the red villous synovial membrane is well seen in the preparation. The crucial ligaments were partially removed, and it was found on dissection that the internal and external lateral ligaments had lost all their distinctness as fibrous bands; both seemed to be resolved and spread out into thin membranes or fasciæ, which but little restrained the movements of the knee, and allowed of a motion of rotation being communicated to the joint. The articular and semilunar cartilages were removed, and the denuded porous surfaces of the bones of the tibia, femur, and patella presented numerous small red spots, as if they had been sprinkled with red sand. An abscess containing about two ounces of yellowish green pus, of a laudable consistence, was found under the cruræus muscle, just above the synovial sac of the joint: this abscess was isolated, and had no communication whatever with the interior of the sac of the joint. The fluid in the interior of the articulation was more of a thin sanies than pus, but was abundant in quantity, and had made its way externally by a large sloughy-looking opening in front of the leg, about two inches below the knee.

Michael Smith, 58 years of age, was admitted into the Richmond Hospital in 1838, labouring under erysipelas of the head. During the course of the disease, one of his knee-joints became hot and swollen, the patella seemed to float, and on each side of it a fluctuation became evident. He was more or less insensible from the erysipelas of the head, but when the knee-joint was moved, he exhibited signs of suffering. On the eighth day after the knee-joint was first affected, he died of the erysipelas of the head. The knee-joint was carefully inspected, fine red injection having been previously thrown into the femoral artery. The synovial sac of the articulation was distended by a turbid yellowish-green fluid, apparently composed of a mixture of pus and synovia. When this was washed away, the synovial membrane was found not so much thickened as in the former case, nor had it so much of the vivid scarlet colour as the last specimen alluded to; and reminded those who examined it of the appearance which the conjunctiva presents in subacute conjunctivitis. This membrane appeared to be thickened and pulpy where it had already advanced somewhat over the external condyle of the femur. The subsynovial tissues were more or less infiltrated. The cartilages had lost their normal whiteness and brilliancy, and were of a murky yellowish hue; they were somewhat softened in their substance, and the cartilaginous covering of the patella was slightly elevated, in patches, and one spot of ulceration was seen at the circumference of its external edge. The cartilage covering this bone was so soft that the blunt probe easily penetrated into its structure. Many would call this a case of simple synovitis genu, but it is manifest that, although the acute disease in the knee originated in the synovial membrane, the other structures of the joint very soon became implicated, and that, at the period of the patient's death, which was only a few days after the first attack of the joint, the term of synovitis of the knee-joint was not sufficiently comprehensive. We have had many opportunities of examining the knee-joints of those who have died of diffuse inflammation, which has occurred in females some short time after parturition, and in those cases denominated puerperal rheumatism, and in cases where the arthritis of the knee or other joints was concurrent with phlebitis; and in such cases we have found the most remarkable phenomena to be,—great effusion into the knee-joint of a fluid which would seem to be composed of equal parts of pus and synovial fluid. This was viscid, of a sea-green colour, and of the consistence of honey. In cutting down to the joint in these cases we frequently met with ill-digested matter in and amongst the muscles surrounding the affected articulation. The synovial membrane was of a pink colour. The articular cartilages presented an appearance which was rather peculiar. We have found them generally to preserve their normal adhesion to bone, to be smooth on their surface, but to be evidently thinned, and so reduced as to form a stratum covering the condyles of the femur scarcely half a line in thickness. The inter-articular cartilages externally preserve their normal appearance, but we can occasionally discover that after an attack of acute arthritis of the description now under consideration, these structures shew that they are permeated internally by capillary vessels containing red blood. We have had many,—too many examples lately verifying the above description of the anatomical appearances presented on the examination of the knee-joints of those who have died of diffuse inflammation.

Simple chronic arthritis of the knee.—The symptoms which denote the existence of simple chronic inflammation of the knee-joint are very similar to those belonging to the acute affection of this articulation, being only slower in the different stages of their developement and milder in their character.

The simple chronic arthritis genu commences with a pain which the patient usually refers to the inner side of the joint. This pain is not sufficient to prevent him from following his ordinary occupation, and is at first usually unaccompanied by swelling, or if swelling exist at this early period, it is inconsiderable. There is more pain and less swelling than in the ordinary case of scrofulous white swelling. The swelling, too, is different, that in the strumous being more elastic, more of a globular form, and situated at first more at the lower and anterior part of the joint around the ligamentum patellæ: in the strumous also the ham is sooner filled up. Moreover, the simple chronic arthritis of the knee is a disease of adult life, and the strumous of the younger subject. As the simple chronic arthritis of the knee proceeds, the limb wastes somewhat, a preternatural effusion of synovial fluid into the joint takes place, and pain on motion becomes so severe as to confine the patient to the house; he complains of a constant, deep, boring pain, which is usually referred to the inner condyle of the femur or tibia, and is accompanied by some spasmodic starting of the muscles of the limb, by which his sleep is disturbed. When pressure is made on the knee over the situation where uneasiness is experienced, the pain is increased; and the integuments of the affected articulation have a higher temperature than natural. In the early stage of the disease the popliteal space is not filled up. As the inflammatoryaction proceeds, the patient's strength and spirits become exhausted by continued pain and confinement; the constitution becomes engaged, suppuration occurs in the interior of the joint, and matter makes its way to the surface, œdema of the instep manifests itself, and the disease now runs very much the same course as does the chronic strumous white swelling, partial dislocation of the tibia outwards or backwards occurring, and amputation becoming necessary to save life.

The two following cases may serve as examples of the simple chronic arthritis genu. The first presented us a rare opportunity of witnessing the anatomical characters of the disease in a very early stage; the second in the advanced form, as amputation could no longer be deferred with safety.

J. M'Cann was admitted into the Richmond Surgical Hospital on the 13th Dec. 1836, for an affection of his left knee-joint. The attack was about six weeks coming on, but he remembered that about ten years previously he had fever, and that the left knee-joint was at that time severely visited by inflammation. Since that period, however, he remained well until he got cold, which ended in the present attack of the knee, and at this time no other joint was affected. The joint appeared to be much enlarged when compared with the right and healthy knee; the prominences of the bones were no longer evident; the swelling was soft and fluctuating, and extended up the front of the thigh, but the ham was not in the least filled up; the knee was slightly flexed, and the tendons of the hamstring muscles were remarkably tense; he referred the pain to the internal side of the joint. Hoping to be released of these symptoms he sought admission into the hospital. He was ordered twenty-four leeches and fomentations to the knee-joint, and to take three times a day a pill containing two grains of calomel and half a grain of opium. On the fourth day of this treatment he complained of scalding when passing urine, and of acid eructations from his stomach. For the latter magnesia and lime-water were given. On the fifth day diarrhœa, probably mercurial, set in, which was very severe and did not yield to the treatment, which consisted in the administration of an emollient enema containing forty drops of tincture of opium, and of a pill every third hour, containing two grains of acetate of lead and one grain of opium; and warm fomentations with turpentine to the abdomen. After the fourth pill had been taken the diarrhœa ceased. It is proper to mention that the foregoing symptoms were accompanied at the commencement by a good deal of fever of the sthenic type; the patient's face was greatly flushed, his eyes glistened, the lips were vermillion red, the pulse was one hundred and strong, and there was much increase of heat of the surface. When the diarrhœa ceased, a new phenomenon, hæmaturia, presented itself, accompanied by great pain across the lumbar region, along the course of the ureters, and in the testicles. The calls to pass water occurred hourly, and half a pint of urine and blood mixed would pass, which had not any urinous odour. These calls became less frequent, but the fluid passed became more and more red; his countenance changed, and he had the general symptoms of loss of blood. Added to this his stomach was in a continued state of erethism; he had urgent desire for cold drinks, but nothing, not even cold water, would for one moment remain on his stomach. His countenance was sunken and exsangueous; his pulse, one hundred and forty, could scarcely be counted. His surface became cold, and he complained of the greatest sense of exhaustion. At this period most urgent singultus set in and added much to his other sufferings. The hæmaturia continued, the stomach rejected every species of nutriment, and medicine failed altogether to relieve his symptoms. He died exhausted on the fourth day from the diarrhœa setting in, and on the seventh from his admission into hospital. It is remarkable that during the last three days of his illness he did not feel any uneasiness in his knee, and the swelling of the joint had greatly diminished.

On a post-mortem examination the kidneys were found much enlarged and friable, with some purpuric spots (petechiæ hæmorrhagicæ) on their surface. The spleen was very small and of a healthy consistence. On opening the bursa beneath the rectus and vasti, it was found to be distended with synovial fluid of the ordinary character; no communication existed between this bursa and the knee-joint. When the proper synovial membrane of the joint itself was opened, the quantity of synovial fluid was found to be very scanty. The semilunar cartilages were normal, but the articular cartilages which invest the tibia and femur were of a yellowish hue, and here and there appeared softer than natural. In one spot the cartilage covering the convexity of the internal condyle of the femur was superficially removed for the size of a sixpence. To this softened, ulcerated, or abraded point the principal pain was referred, by the patient during life. There were not any loose and vascular synovial fringes hanging into the interior of the joint, but examining at the circumference of the cartilage, where it invests the external condyle of the femur, this membrane and its subsynovial tissue were very red, vascular, and villous-looking. The outer edge of the cartilaginous covering of the femoral condyle was thin and minutely serrated, and the eye of the probe could be placed under this edge.

John Nugent, æt. 19, was admitted into the Richmond Hospital, January, 1839. He had been under treatment in the country for six months for a disease of the left knee-joint which originated in a blow on the joint from the handle of a printing-press. He fainted at the time of the accident, and the pain never ceased from that day up to this period of his admission. He was reduced a good deal in flesh. He had occasional perspirations during the night, particularly about the head, and starting pain shooting up and down the leg. He could not bear the joint to be moved but kept it semiflexed, and the limb lying on the outside. He stated that before his admission he had never been altogether confined for the complaint. There was some little swelling of the knee, which was tender on pressure. There was no swelling in the ham, nor enlargement of the inguinal glands. The calf of the leg was wasted, and the thigh also was less than the other by an inch in the measure of its circumference above the knee. He remained much in this state until March 14th, when he complained of suffering a constant "dead pain" across the joint below the patella; besides this there was occasionally a throbbing sensation which was more distressing to him than any other, even than the spasmodic starting of the limb. On the 2nd of April a valvular opening was made with caution into an abscess on the inside below the articulation; thin curdy matter came away. This gave him some relief. On the 4th another opening was made in the outside above the joint, where also the abscess showed itself: matter of a similar description came away. Previous to these punctures having been made, amputation was proposed to the man as the only means of escape from this disease, but he preferred to have the abscesses opened. Fever did not follow upon this first or second operation, but subsequently it set in, and ran very high for four days, during which he perspired largely and had much pain and starting of the limb, with head-ache and anxiety of manner, and for two days he was in a confused state bordering on delirium. Nor did the evacuation of the purulent matter prevent the enlargement of the cavities of the abscesses connected with the diseased joint, as appears by the following report, dated May 10th, made by our clinical clerk, Dr. Bradshaw. "The abscess has ascended up the thigh, running high up the popliteal region. The hectic fever is severe; his pulse in general 120, small and compressible; emaciation had advanced and is still advancing; his strength is giving way under the disease, and he must soon sink if amputation be not consented to." On the 10th May the report was, "Diarrhœa still continues, but without abdominal pain or tenderness. The emaciation is very great. Pulse 120, small, and compressible. Tongue red, moist, and morbidly clean. The flexion of the leg on the thigh becomes every day more and more considerable, so that the angle becomes daily more acute." On the following day amputation high up was performed. The disease of the knee had much affected the cartilaginous structures of the joint, the absorption of which seemed to have been effected by a vascular pulpy membrane. The parts that had suffered most were the external condyle of the femur, the inner head of the tibia, and the inner and posterior surface of the patella. Along the trochlea of the femur there existed longitudinal grooves or furrows in the cartilage, which was not removed. A highly vascular and pulpy membrane was found filling the parts wherever the cartilage had been absorbed, and this membrane could be traced insinuating itself beneath the edge of the remaining portions of the cartilage, by which means the process of absorption seemed to have been effected. In the interior of the joint there were much pus and flakes of lymph, and where the cartilages had been removed the porous surface of the bones had been covered by soft layers of lymph of very recent formation.

Chronic rheumatic arthritis of the knee.— In the articles Hand, Hip, Elbow, &c. in this work we have treated of a chronic disease affecting other articulations, which we have denominated *chronic rheumatic arthritis;* we shall now give an account of the symptoms and anatomical characters of this disease as we have found it in the knee-joint. When this articulation is affected with it, other joints in the same individual will also be found more or less implicated. The commencement of this disease of the knee is marked by evidences of subacute inflammation, such as pain, heat, considerable swelling. This is followed by a second period, in which the heat and swelling diminish, but the pain continues. This pain is usually referred to the inner condyle of the femur and tibia. The patient may for a long period be able to walk, but every movement produces considerable pain, and at length he becomes incapable of walking or even of standing. The limbs diminish in size, but become remarkably firm to the feel. The patient having at last lost the power of flexing or extending the limb, the hamstring muscles gradually become more tense. The knee-joints from the commencement incline slightly inwards, and the tibia outwards, and this bone is at the same time rotated in this last direction, so that the foot is everted; if the limb then be kept in the semi-flexed position, and the tibia be thus rotated outward, carrying with it the ligamentum patellæ, it is easy to account for the circumstance which we have in some examples witnessed in the disease,—viz. that the patella leans towards the outer condyle, and further, that it is then sometimes thrown completely over it, so as to represent the external dislocation of this bone.

When the distension of the synovial sac of the articulation is at its maximum, we usually notice in this disease a prominent tumour about the size of a small hen's egg projecting into the popliteal space (*fig.* 3). This tumour leans towards the inner head of the gastrocnemius; it disappears when the knee is flexed, and becomes more tense and hard when the limb is in the extended posture, as when the patient stands erect. We have known several cases of this disease of the knee-joint, where the synovial sacs of the knees have been much distended, and have on these occasions almost uniformly observed this popliteal tumour formed. From its situation, and from negative evidence, we can readily infer that the swelling consists of synovial fluid contained in a bursa, which has a communication with the interior of the knee-joint.

We have witnessed very many cases of this chronic rheumatic arthritis of the knee, in which this dropsical condition of the popliteal bursa existed, and some of these having had this chronic disease in both knee-joints, the bursæ were seen in both popliteal spaces,—presenting in these cases on a superficial inspection the resemblance to a case of double popliteal aneurism.

We have also enjoyed an opportunity of ascertaining by anatomical examination the real condition of this synovial sac in this disease, and its relation to the synovial membrane of the joint itself, to which we shall have occasion just now to revert.

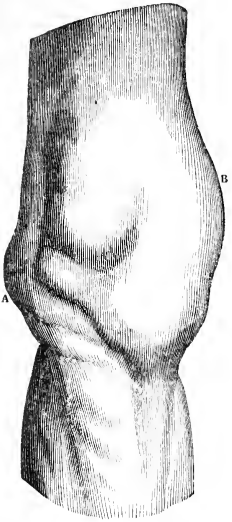
When the palm of the hand is applied over the patella in the early stages of the affection, a sensation of a preternatural degree of heat is felt; and when pressure is made on the patella, and a lateral movement across the condyles is communicated to it, a very evident roughness is perceived, either on the articular surface of the patella itself, or the corresponding surface of the trochlea of the femur; and when the knee-joint is fully flexed, a characteristic articular crepitus becomes manifest. In the later stages of the disease, the subacute inflammation, with the phenomena which it presents, subsides, the synovial fluid becomes absorbed, and the patella falls down on the trochlea of the femur; the popliteal bursa also disappears, and the grating produced by rubbing surfaces is perceived by the patient himself in all his movements, and can even be heard by the bystanders. If the joint be now examined carefully by the surgeon, he feels satisfied that the smooth cartilage has been removed, either partially or completely, from the articular surfaces. Crests of ossific deposit may even be perceived, and, almost invariably, foreign bodies may be felt in the interior of the joint. Some of these are superficial, small, and moveable; others are evidently situated more deeply in the interior of the joint. Some are small, some large, and we have known one case, which we learned to be of forty years standing, in which numerous bodies* of this description could be felt, some literally as large as the patella, floating about in the interior of the knee-joint, and which, we doubt not, were exactly of the same nature as those we have described in the elbow-joint.

The prognosis in this disease must be unfavourable, as it seldom yields to medicine, but it does not appear to us to shorten life. We have seen an example in which the knee-joints had been affected with this disease, as the patient herself reported, for forty years. We are not prepared to say, however, that medicine and proper treatment may not occasionally cut short the disease, and we are sure the sufferings of the patient may be palliated at least by appropriate treatment. The following case is a good example of this disease.

Case of chronic rheumatic arthritis.—Patrick Donohoe, aged 38, a carter, admitted into the Richmond Hospital, (Dublin,) Nov. 24, 1836, complained of chronic pains in all his joints, but the principal source of his uneasiness was the diseased condition of his knee-joints, which prevented his earning his livelihood. Both knee-joints were greatly swollen; he complained of stiffness of them, and of some pain at the inner condyle of the tibia, which increased when he stood up; yet he was able to walk a considerable distance. The limbs could be fully extended, and when in bed he kept them pretty constantly in this position. He could not fully flex them backwards. The swelling of the knees differs from that of an ordinary white swelling, although it might correspond much to the characters which a case of chronic synovitis of the knee might present, or to a case which the older writers denominated *hydrops articuli*. The swelling viewed in front is of an irregular globular form, involving the patella, its ligament, and the hamstring tendons in one uniform tumour; on the contrary the ligamentum patellæ can be felt, with its edges as yet sharp and well defined, when the patient is desired to exert the extensor muscles of the leg. The tibia at the side of the ligament, as far as the insertion of the internal lateral ligament, can be plainly felt through the skin to be rough and scabrous, and it can be perceived that this part of the bone is beset with bony vegetations. The breadth of the head of the tibia is increased; the synovial membrane contains a redundant secretion, which elevates the vastus internus and forms a swelling here which measures about seven inches in its vertical diameter, and which seems to be somewhat constricted transversely in its centre (*fig.* 2). The swelling of the knee on the outside is evident enough, but is not so well marked as that on the inner side. It presents no transverse band, subdividing it into two tumours. The outline of the hamstring tendons is seen, when the joint is viewed in profile, either from without or within, and a very well defined ovoid projection from the popliteal space is observed (*fig.* 3). Its centre is on a level with the up-

* The case mentioned by Morgagni in which he saw twenty-five of these bodies in the left knee-joint of an old woman who died of apoplexy, we think must have been a case of the chronic disease we are now describing.

Fig. 2.



Left knee-joint, front view.
The prominent swelling on the left, A, is from the enlarged head of the tibia; that on the right, B, is the soft globular swelling resulting from the effusion into the synovial membrane.

Left knee-joint, side view, shewing the enlarged bursa in the popliteal space.

per and projecting margin of the inner condyle of the tibia: it leans to the inner hamstring muscle. The rest of the popliteal space presents a normal appearance. When the limb is fully extended, and the muscles are allowed to remain in a passive state, the patella may be moved from side to side with much freedom. It appears to float as it were on the surface of an accumulated quantity of synovial fluid. When pressed against the trochlea of the femur, this fluid is moved laterally, and the patella strikes against the femur, and if a lateral movement be now communicated to this bone, a grating of rough surfaces may be perceived. If we grasp the leg and flex it on the thigh, we find we can elicit a peculiar articular crepitus. In this case it is quite audible, and resembles much the noises which electric sparks make when discharged in quick succession from an electrical apparatus. When the limb is much flexed, the swelling of course feels remarkably hard and solid, but when the limb is again brought back to its ordinary state of extension, fluctuation may be felt very evidently in it over its whole surface. The popliteal bursa, however, is felt very tense in the extended position of the joint, as when the patient stands and throws his weight on the limb. If we feel this bursa, and then cause the patient's limb to be flexed, we can follow the fluid, as it were, with our fingers into the articulation. As the patient lies in bed, the limb left in the extended position, and the synovial sac as flaccid as possible, moveable bodies may be detected in its interior. Some appear to be adherent, and situated more particularly in the upper portion of the subcrural bursa. When we elevate the leg, and preserve it still in the fully extended position, the patient, without any apprehension of pain, will permit us to press it firmly against the femur, and does not experience the least suffering even if we strike the heel forcibly. (See HIP, ABNORMAL CONDITION OF.)

Both knee-joints in this case are affected with this disease, but the left is more distended by fluid than the right. The inner condyles of the femur and tibia of this limb are thrown somewhat inwards, and form a salient angle in this direction, which, the patient says, is certainly the result of disease, as his limbs were perfectly straight before he was visited by his present illness.

Although his knee-joints are more affected with this chronic disease, his other joints present very evident traces of this afflicting malady. The disease in him followed a rheumatic fever, which was brought on in consequence of his having lain a whole night asleep on a wet road, having fallen unobserved from his cart when in a state of intoxication.

Although this is not the place to speak of treatment, we may be permitted to say that under the influence of rest in bed and a mild mercurial course, followed by a long-continued use of sarsaparilla with large doses of the hydriodate of potass, this man left the hospital, by no means cured, but much improved and tolerably well able to follow his occupation.

He found it necessary, however, after the lapse of three years, to seek re-admission into the hospital, where he now is. The right knee-joint is now enlarged, and in a condition similar to that of the left on his first admission. The latter, on the contrary, has nearly resumed its normal condition; the dropsical effusion of synovia has disappeared; he does not complain of pain in it; but if the joint be accurately examined, the bony irregularities which were noticed on the head of the tibia will be found, as might be expected, still to exist. If we move the patella transversely, an articular crepitus is perceived, plainly shewing that the cartilages have been removed from the patella and corresponding trochlea of the femur. The edges of the trochlea can also be felt through the skin to be elevated into rising crests. The peculiar crackling noise which is elicited when the joint is flexed and extended is infinitely more remarkable in the left knee-joint now, when it is comparatively well, than formerly, when it was much swollen, and when the synovial membrane was in what has been called a dropsical condition.

Anatomical characters.—When we have an opportunity of making an anatomical examination of a knee in which the disease had been fully established, we find the synovial fluid increased in quantity, and but little altered in its sensible qualities. The membrane is thicker than natural, and opaque. Sometimes vascular synovial fimbriæ are formed, and hang into the synovial sac.* We also find moveable cartilaginous bodies in the interior, similar to those noticed in the elbow-joint.† (See ELBOW, ABNORMAL CONDITIONS OF.)

In the line of flexion and extension we observe narrow sulci formed by the removal of the cartilages. On examining the popliteal tumour, we find it to be, what we might have surmised, an enlargement and dropsical condition of the bursa, which naturally exists at the point of decussation of the semi-membranosus tendon with the tendon of the internal head of the gastrocnemius. This bursa communicates normally with the synovial sac of the knee-joint by a very small circular aperture. It is not an uniform ovoid sac, but evidently has semilunar septa irregularly thrown across its interior, making the bursa a small multilocular cavity. When the joint is much distended by synovial fluid, the bursa admits some of this fluid, and takes upon itself the same morbid process which affects the proper synovial membrane of the joint itself. As we examine the disease when it has existed for some time, we find that the cartilage has been removed in grooves, and its place supplied by a porcelainous or ivory deposit. The bones of the knee-joint, however, present appearances characteristic enough: they generally appear to be enlarged. This is obviously the case with the patella: it is broader than natural, excavated, and grooved vertically. All the bones seem enlarged and porous on all those parts of the articular surfaces which have not been worn by use into porcelainous polished surfaces and sulci.

The cavities of the head of the tibia for the reception of the condyles of the femur are much deepened, and exuberant nodules or vegetations of bone are thrown out around the circumference of this head. When we examine the femur, we find here also bony vegetations, arranged along the lateral margins of the condyles, similar to those which we noticed around the corona of the head of the femur.* The part of this bone called the trochlea, upon which the patella moves, is also grooved vertically, and the trochlea has rising edges to it, or crests, which will be found to correspond to the lateral margins of the patella when this bone is laid upon the trochlea of the femur. The anatomical characters of this disease when it has existed long, will of course be still more strongly marked. However, the dropsical effusion into the synovial sac will be found to be much less as the disease is of longer duration. The joint becomes more and more flexed, the tibia has a tendency to be partially displaced outwards, and the toe is everted: the patella under such circumstances is dislocated on the external condyle, giving us another example of this luxation from disease. In the interior of the joint foreign bodies are found, while the articular and semilunar cartilages are altogether absorbed.

White swelling, or chronic strumous arthritis of the knee.—The knee-joint is more liable to the disease commonly called white swelling than any other articulation. This disease, though utterly insidious in its attack and slow in its progress, nevertheless presents some of the characters of an inflammatory complaint during its whole course. The first symptom generally is reported as a deep-seated dull heavy pain unattended by swelling and not increased by motion, but in children the swelling is often the first symptom noticed. This is followed by pain, which, although it comes only occasionally, is severe, and is referred almost uniformly to the inside of the knee. Some increase of temperature of the affected joint on comparison with the other knee, can be ascertained.

The swelling does not at first encompass the whole joint, but first appears on the anterior and lower part of the knee, occupying in general the two little hollows on the different sides of the ligament which joins the patella to the tibia. This swelling is elastic, and on examination by the finger conveys a sense of softness and fluctuation, as if it contained a fluid, although no fluid to any amount really exists. The skin over the knee becomes pale and shining, as if thinned. The subcutaneous veins dilate and become very evident. The muscles of the leg waste, so that the volume of this portion of the affected extremity is considerably reduced, and the inferior part of the thigh just over the knee suffers a characteristic diminution in the measure of its circumference.

* See Cruveilhier, liv. 9. pl. 6.

† See Morgagni's case, in note above.

* See HIP, ABNORMAL CONDITION OF, *fig.* 310; also Cruveilhier, liv. 9. pl. 6. *fig.* 2.

Patients under an incipient attack of white swelling first experience inconvenience in walking from weakness of the joint, a symptom which is more especially troublesome after exercise. But as soon as the pain becomes constant, the patient is no longer able to rest the weight of his body upon the affected limb without a great increase of uneasiness. On this account he is willing to save the limb as much as possible; he touches the ground, therefore, merely with his toes, trusting the support of his body chiefly to the other limb. In walking in this way the knee necessarily becomes bent, and what is thus begun becomes permanent from other causes; so that after a certain period the joint continues permanently in a state of flexion.

Although we occasionally see cases in which the leg remains extended on the thigh, they must be considered rare, for in general the leg is in a more or less forced state of flexion on the thigh, and such is the patient's apprehension of pain he will not on any account extend the leg voluntarily, nor allow it to be extended by others.

The earlier period of the disease is succeeded by a second stage,* in which the patient usually submits to the adoption of active and energetic treatment. The pain now not unfrequently diminishes, but the swelling continues increasing, the ham becomes fully occupied by it, the extremities of the bones appear to enlarge, and become more prominent as the flexion increases. Attacks of inflammation ensue, accompanied by pain starting up and down the limb, by which sleep is interrupted. These attacks are usually succeeded by effusion of fluid into the synovial sac of the joint and cellular interstices around: abscesses form, and some fluctuation may now be discovered in different parts of the swelling. If at this period, which may be called the third or suppurative stage of the disease, the bones be moved laterally, it will be perceived that the ligaments permit an unnatural degree of motion between them, and now, as in other articulations, partial or complete luxation may occur. Such, however, is the breadth of the surfaces of contact of the bones of the knee-joint, that *complete* luxation seldom happens. The limb at this period is usually found lying powerless on its outer side and in the semiflexed position; and after some time a partial displacement of the leg outwards on the femur occurs: under other circumstances a partial or complete luxation backwards happens. Although the disease, arrived at this stage, seldom terminates favourably, still instances do occur of unexpected improvement of the general health, of the resolution of the swelling, of the absorption of matter, and of one of the forms of anchylosis taking place. But usually the matter formed in and around the joint goes on accumulating, the tension of the knee-joint increases, and now in most cases an accompanying œdema of the foot is observed, a symptom than which there can be none more unfavourable. The nocturnal startings of the limb, disturbing the patient's rest, become more painful and urgent, and abscesses communicating with the interior of the articulation open externally by one or more orifices, and give exit to a quantity of matter, which rarely has the quality of laudable pus; on the contrary, it is for the most part a sero-purulent liquid, of a yellowish green colour, like whey, in which curdy matters are found floating. It is remarkable that little diminution in the size of the swelling follows the escape of this matter.

We have stated that the pus is seldom laudable. On some few occasions, however, its consistence may be that of good pus; but even then it soon degenerates into a thin fœtid sanies of bad quality. The openings giving exit to the discharge sometimes close very speedily, and new collections form in different parts of the tumour. This, however, is unfortunately rare, for generally the openings degenerate into fistulæ. A probe introduced into one of these penetrates, if the route be not long and circuitous, into the interior of the joint, and discovers the internal parts to be carious and disorganised; and if the bones of the articulation be now pressed together, a crepitation, arising from the friction of the carious and ulcerated surfaces, is perceived, furnishing unequivocal evidence of the last stage of disorganization of all the structures of the articulation. This is the most common course of the disease, but in some cases there are varieties to be observed. For example, the suppuration of the soft parts and of the cartilages, and even caries of the bones, may occasionally precede the displacement of the bones; and all the parts of the articulation may be destroyed without the occurrence of any displacement; but if, in this case, we move the bones of the articulation in opposite directions, we easily ascertain the relaxation of the uniting ligaments, and that many of the conditions necessary to the displacement exist, although, from some cause not easily explained, it has not occurred.

As to our prognosis we should remember that the age and constitution of the patient have considerable influence on the ulterior progress of the disease, and our knowledge of this must control our anticipations as to the result to be expected, *cæteris paribus.* The disease in the truly strumous subject is very rebellious, and has a disposition to terminate in suppuration which it is difficult to baffle. In young subjects it is in general more acute, or the succession of the different orders of symptoms is more rapid; but in young persons there is much more hope of cure than in the old and exhausted. We agree with Mr. Russell in opinion that it is in the cases of infants that the formation of anchylosis may be expected as the termination of a case of white swelling, though even with these true bony anchylosis must be considered as a very rare occurrence.

In the beginning the disease has but little

* Mr. Lloyd divides scrofulous white swellings into three stages; the first being that in which the affection is confined to the bone; the second that in which the external parts become thickened and swelled; and the third what he denominates the sub-acute stage.—*Lloyd on scrofula.*

influence on the constitution: it is not until it arrives at the second or third stage that it produces any very remarkable alteration in the health; but the pain about the commencement of the third stage is sometimes so violent as to deprive the patient of sleep and appetite. When the part is distended by abscesses, the pain is increased, but when these open or are opened, although temporary relief follows, slow fever supervenes, the discharge becomes sanious and fœtid, and nocturnal sweats and colliquative diarrhœa shew themselves, together or alternately.

Anatomical characters of the chronic strumous arthritis of the knee.—The anatomical examination of a limb which has been amputated on account of a white swelling, or after the death of the patient, demonstrates different alterations which disease produces in the structure of the soft parts surrounding the diseased articulation, and in that of the bones, synovial membranes, and cartilages which compose it. The skin and subcutaneous cellular tissue are not greatly altered from their natural condition, except that the latter is usually infiltrated with a gelatinous matter, as is also the cellular structure, which lies deeper, viz. that which unites the femur with the inferior part of the cruræus muscle, as well as that behind the ligament of the patella, and that also which occupies the intervals between the condyles of the femur behind the crucial ligaments. These parts are equally infiltrated by a gelatinous fluid, of more or less density. The whole of this cellular structure presents the appearance of a soft, spongy, homogeneous mass. The ligaments which secure the junction of the bones of the joint seem themselves involved in this morbid change of the surrounding cellular structure, so that the tumefied ligaments and other structures seem to be confounded together, and to present an appearance almost like a fibro-cartilaginous mass. "Thus have we seen," says Boyer,* "the fatty cellular tissue which is placed behind the ligamentum patellæ, so dense and thickened that it formed but one mass in which ligament and cellular tissue seem confounded together." All these appearances are present even before suppuration has occurred. If the disease had existed for any length of time so as to have arrived at the period of suppuration, we find, among the structures thus altered, that symptomatic chronic abscesses have been formed. One extremity of them we observe usually communicating with the knee-joint, while the other reaches the surface, and presents one or more openings which had become fistulous. These abscesses and fistulous canals we find always lined by a false membrane. The muscles which surround the diseased joint are pale and wasted, and the cellular tissue which is found in their thickness is ordinarily more or less infiltrated with the peculiar glairy matter above alluded to. The tendons of the flexor muscles are generally retracted and preserve their normal appearance. The nerves we have had occasion to observe to be thicker than natural. These are the alterations which are noticed in the soft parts, as we pursue an anatomical examination down to the bones and ultimate structures of the joint itself. It is probable, however, that these changes will not be found to have occurred unless the disease has existed for some time previously in the centre of the bones themselves. Sir B. Brodie, Lloyd, and others are of opinion that this strumous disease begins in the centre of the heads of the bones of the knee-joint, in the cancellous structure;* and Rust has satisfied himself that the membranous tissue which lines the cancellous structure of the bones is the seat of the first morbid action. They have found the interior of the spongy tissue of the bones more vascular than natural, and with much apparent justice conceive them to be inflamed. These changes, then, in the interior of the bone they believe to constitute the anatomical characters of the first period of the disease, and that when the parts external to the joint become swelled and infiltrated by the gelatinous matter above alluded to, the second period is fully established.

When the second period has commenced, and the soft parts are excited into irritation, if opportunities occur of examining the interior of the bones, they will be found to be softened and easily penetrated by a knife. The synovial membrane contains an unusual quantity of fluid, and the bones will undergo further changes as the disease grows worse. These structures become still softer, thei- cancellous structure is found filled with a yellowish cheese-like matter. The bones, which in the first period were in an hyperæmic condition, are now found to be less vascular, and portions even become necrosed, so that it is not uncommon in advanced cases to find in the interior of the joint portions of dead bone. In these cases the spongy portion of the bones seems so altered in structure as to appear half dissolved, and to contain a sanious and fœtid matter in its substance. The periosteum investing the bones in the neighbourhood of the diseased knee is very much thickened and easily detached. It is surprising to what an extent this strumous disease may have advanced in the bones and in the external parts around the joints while the synovial structures and cartilages remain but partially engaged. The writer has lately been compelled to amputate a thigh for this disease of the knee in consequence of the constitutional symptoms which it excited in the system. In this case he discovered that while the bones and soft parts externally were far advanced in the second stage of the disease, the synovial membrane and cartilages were perfectly natural. When, however, the disease has advanced far, and the fistulous orifices are found to communicate with the interior of the joint, we find that the synovial membrane presents appearances of morbid action having gone on in it, and when the puriform fluid contained in it is wiped away, that the surface of this mem-

* Maladies Chirurgicales.

* Russel entirely differs from them.

brane, instead of being white, is red and villous, and much like mucous membrane in a high state of inflammation. We can frequently ascertain that this membrane has superadded to it layers of newly deposited lymph, which have become highly organized. Mr. Russell says, that in his dissections of white swelling of the knee, he has found the inside of the synovial membrane covered with a layer of a soft substance, of a pale yellowish colour, and semi-transparent; that this substance was nearly one-eighth of an inch in thickness, softer in its inner concave surface, and firmer on the outer convex part, where it adhered to the inside of the synovial capsule of the joint with a considerable degree of firmness. In many places he observed on it a very beautiful plexus of vessels; and at the interstices between the surface of the femur and tibia, he states that he generally found an appendage full of blood-vessels which had insinuated itself to the distance of nearly half an inch. It very frequently happens that the cartilages and crucial ligaments are completely concealed from our view by a membrane, in some places of one-quarter or even one-half of an inch in thickness, presenting a loose cellular structure, highly vascular, occupying the intervals between the condyles, and hanging into the interior of the joint; and we have usually found this newly-formed structure to be superadded to the original synovial membrane, and to establish adhesions between the bones of the articulation, and we find bands of organized lymph stretching from the femur to the tibia. When this condition of the synovial membrane existed, we have usually found the cartilages remaining; but in other cases the synovial membrane itself has been found to be but little altered; and yet the cartilages have been removed partially or completely, the porous substance of the bone having been found exposed, or covered by recent deposits of soft pultaceous lymph.

Such are the organic changes which usually produce white swellings. These changes present numerous varieties, but it is sufficient to notice the principal ones, and to observe that there are scarcely two patients in whom they are perfectly alike.

Sir Benjamin Brodie, in his work on the joints, has remarked that when acute inflammation attacks the shaft of a cylindrical bone and the periosteum covering it, the disease is usually limited by the epiphysis, so that, notwithstanding the extensive abscesses and exfoliations which frequently ensue, the neighbouring joints are not affected by it. Although we have seen numerous specimens proving the general truth of this observation, yet on the other hand we have witnessed exceptions to it: indeed Sir Benjamin Brodie has further observed that a few instances occur in which acute inflammation attacks the epiphysis itself, terminating also in exfoliations, &c. more or less extensive.

In very young subjects we occasionally see examples of diffuse inflammation which has engaged the periosteum of the femur or tibia, and the epiphysis of one or both of these bones, the inflammation extending to the knee-joint. These cases are usually rapid in their course, and too frequently terminate fatally, the ordinary symptoms of diffuse inflammation being exhibited in their progress. In the *post-mortem* investigations of these cases we find that the periosteum is extensively separated from the bones by purulent matter; that the epiphyses, detached from the shafts of their respective bones, are loose in the interior of the joint; and that the synovial membrane is distended by matter. In the serous and mucous membranes of the chest also we generally find evidences of acute inflammation having existed. The origin of these violent attacks is sometimes referred to a fall or other accidental injury, sometimes to a cold which commenced with a rigour. We have sometimes known this severe form of disease to succeed immediately to attacks of small-pox, and also of scarlatina. Dr. M'Dowel, in the third and fourth volumes of the Dublin Journal, has described this disease under the heads Periostitis and Synovitis; and the museum of the Richmond hospital contains many specimens of these unhappy results of diffuse inflammation.

Cases of diffuse inflammation are not the only ones in which we have seen matter, formed beneath the periosteum of the tibia, passing the epiphysis and getting into the cavity of the knee-joint; we have known instances of such occurrences in cases of acute necrosis of the tibia, in which the disease in its commencement had been exclusively confined to the one bone. Mr. Smyly, one of the surgeons to the Meath Hospital, presented to the museum of the College of Surgeons in Dublin, a specimen, the result of an acute necrosis of the tibia. The following is the history of this case, which he kindly communicated to the writer. James Jarman, æt. 9, was admitted into the Meath Hospital the 5th October, 1837. Sixteen days previously he had suffered a very severe contusion on the front of the left tibia by the accidental falling of an iron bar; there was, however, no breach of the skin, and the boy was able to walk about as usual for two days, when acute inflammation attacked the contused part, and daily increased for a fortnight. On the 4th of October he applied for relief at the dispensary. At this time a large and tense swelling extended from above the knee to the instep; a fluctuation was evident the whole way down the front of the leg. An incision was made into this swelling, which gave exit to a considerable quantity of thin discoloured pus, and the tibia was found quite denuded of periosteum. Great relief followed the opening of the abscess, but on the 10th of October there was much tumefaction observable at each side of the patella, and redness, as if the joint were in a state of suppuration. The boy suffered much from irritative fever and occasional diarrhœa: his pulse became very frequent, and his tongue red and dry. The operation of amputation at the lower third of the thigh was now the only resource, and it was accordingly performed.

On examination, the knee-joint was found distended with purulent matter. The synovial membrane was covered in patches by a vascular pulpy membrane; the cartilages were removed in several places. An opening was found *in the inner condyle of the tibia, which perforated the spongy substance of this bone*, and thus established a communication between the interior of the knee-joint and a large abscess as it were which had formed under the periosteum of the tibia. The shaft of the tibia was detached from the epiphysis and the periosteum, and was surrounded by matter. The periosteum was thickened, vascular, rough, and gritty from minute particles of bone deposited in it. The ankle-joint was free.—The boy recovered his health.

Acute arthritis of the knee may be combined with acute osteitis of the bones of this articulation, and without any discoverable communication between the cavity of the articulation and the interior of the bones. On the 21st March, 1840, Mr. Smith presented to the Pathological Society the following case. Susan Christie, æt. 56, an inmate of the House of Industry, and for a long period disabled by the affection of the knee-joints which we have described as *chronic* rheumatic arthritis, was removed to the Whitworth Hospital, where she died of a most acute attack of inflammation of the right knee-joint. On the post-mortem examination old adhesions were observed in the chest. The right knee-joint presented the external appearances noticed as belonging to the chronic rheumatic arthritis in a somewhat advanced stage; moreover, it was greatly swollen, and when the synovial membrane was opened purulent matter escaped; organizable lymph lined this membrane and the cartilages generally. These structures, however, were in some places removed altogether, their place being supplied by a porcelainous deposit, grooved in the line of flexion and extension. From the condyles of the tibia the cartilage was raised up from the bone, apparently stretched out, and converted into a thin, flexible, and soft yellow membrane, difficult to be distinguished, except by its situation, from a deposit of lymph the produce of recent inflammation.

But the interior of the head of the tibia, its cancellated structure, the medullary membrane lining these cancelli, and the membrane of the medullary canal itself, all presented evidences of their having been the seat of acute inflammation. The purulent matter was diffused through the cancelli of the tibia, from the knee-joint, for one-third of its extent, but was nowhere collected into any isolated cavity or abscess, nor was there any communication between the purulent matter which occupied the synovial sac of the knee-joint, and that which pervaded the medullary structure and cancellated tissue of the tibia. In a word, the anatomical characters of a true acute osteitis of the bones entering into the formation of the knee-joint coexisted in an advanced stage with those of acute inflammation of all the other structures of the articulation.

The osteitis of the lower extremity of the femur or upper portion of the tibia *sometimes* presents more of a chronic character. The inflammation of the interior of the bone may proceed to cause the death of a portion, which is converted into a sequestrum, the presence of which becomes a source of irritation and inflammation of the surrounding bone and the formation of an abscess. The following case came under the writer's observation while under the care of his colleague Dr. Hutton in the Richmond Hospital. Thomas Conolly, æt. 43, was admitted in May, 1838, for a disease in the lower extremity of the left femur, of many years' duration. He had long suffered from a deep boring pain in the interior of the bone. At length an abscess formed, matter made its way to the surface and was evacuated, and two small fistulous openings remained, through which a probe could be passed deep into the interior of the enlarged femur. The man was greatly exhausted by the quantity of the discharge, by confinement, and hectic fever, and amputation was performed in the femur just above the diseased part. The femur was found much enlarged near the knee-joint, and covered by wasted muscles, which had undergone a considerable degree of fatty degeneration. When these were removed, the periosteum was found thickened. A vertical cut from before backwards was made through the femur, knee-joint, and tibia, by which section the cavity of an abscess capable of containing a hen's egg was exposed, which was placed transversely between the condyles, having two open fistulous orifices, one on the inner, the other on the external condyle. This abscess was lined by a thick membrane which by a fine injection was proved to have been highly vascular; villous flocculi hung from it into the interior of the cavity; a dark-looking sequestrum of a cylindrical form, an inch and a half long and half an inch thick, occupied the superior half of the cavity; one end of the sequestrum was fixed into the bony tissue of the femur, as if it were on its way to present itself at the outer fistulous orifice; the remainder of it lay diagonally across the cavity of the abscess, the front wall of which was principally constituted of soft parts, the femur having been absorbed in this situation. In the vicinity of the abscess, particularly above it, the bone was greatly thickened, its cancellated structure solidified, and rendered apparently as dense as ivory. The interior of the joint was quite unconnected with the cavity of the abscess, but the joint itself presented evidence of its having been at one time the seat of some form of inflammatory action, because the shape of the condyles of the femur was somewhat altered, and at the same time the tibia was partially displaced backwards, and ligamentous anchylosis had taken place. The cartilage had been removed somewhat from the ends of the bones, and its place supplied in patches by a membrane like periosteum, and in other situations by a dense polished enamel. It was to be inferred from the appearances which the bones and contiguous structures presented, that the knee-joint had latterly been quite useless.

Abscess may, however, form in the interior of the heads of the tibia or lower extremity of the femur without being preceded by the death of any portion of the bone, as is proved by a specimen in the museum of the Richmond Hospital. A child, aged about twelve, had long suffered from chronic disease of the upper portion of the tibia. A chronic symptomatic abscess pointed and opened spontaneously in the popliteal space, and here a fistulous opening remained discharging a quantity of thin sanious pus. While under treatment for this chronic disease, a sudden attack of acute arthritis set in, which threatened the patient's life, and amputation was immediately performed. Upon examination of the knee-joint and of the interior of the bones, which were exposed by a vertical section made from before backwards, an abscess was discovered in the centre of the head of the tibia, capable of containing a walnut. This communicated with the popliteal abscess, which had long had a fistulous opening in the ham; but the abscess in the interior of the tibia was now found to have another opening into the cavity of the knee-joint, which had all the appearance of having been quite recent. The matter of the abscess of the tibia having suddenly made its way into the cavity of the knee-joint was the immediate exciting cause of the acute arthritis genu, evidences of which were seen in a layer of lymph which invested the synovial membrane and the cartilages. The patient ultimately recovered.

When the chronic form of necrosis affects the tibia and the epiphysis is included in the disease, the knee-joint sometimes remains but little altered, but in other cases remarkable changes in its form take place. The leg is sometimes fully extended, and is even in advance of the natural line, but it is more generally flexed on the femur, and the tibia is at the same time somewhat curved into the form of an arch, the concavity looking forwards. We have frequently known displacement of the superior head of the tibia, where it enters into the formation of the knee-joint, to take place *backwards* towards the popliteal space. This displacement is usually incomplete. We have examined many living examples of this deformity, and have had a few opportunities of investigating the anatomical changes the joint has been subjected to.

Many circumstances tend to influence the direction in which the luxation may take place. The position in which the limb is preserved during the attack of inflammation of the tibia is one of the most influential. As the limb is generally flexed during the first stage of the disease, the partial luxation backwards will be the one most likely to occur. In these cases, whether the femur or tibia close to the knee be the seat of the necrosis, more or less of effusion takes place into the synovial sac of the knee-joint; all the ligaments of the joint become softened and relaxed; and the action of the hamstring muscles overcomes the resistance of any remaining structures, and the tibia is dislocated partially backwards.

Mr. West, surgeon to the Longford Infirmary, sent to the writer of this article the leg and knee-joint of a man who had long contended against the consequences of a chronic necrosis of the tibia. There were from time to time exfoliations of bone, and a continual discharge of a thin sanious matter which so reduced the strength of the patient as to render amputation necessary. A cast of the limb, taken by Mr. Smith, and the bone are preserved in the museum of the Richmond Hospital, (*figs.* 4 and 5,) from which it will be observed that the

Fig. 4.

Displacement of the tibia backwards from necrosis.

displacement of the head of the tibia was partially backwards. This bone was drawn also somewhat upwards, passing inferiorly so far round the condyles of the femur that the articular surfaces were almost abandoned. This is the simplest form of displacement of the tibia at the knee-joint from disease which we have noticed as the result of a chronic process of necrosis. We have seen some instances of necrosis in which the whole leg and foot were greatly rotated outwards on the femur, so that the inner ankle was placed directly forwards, and the outer malleolus directly backwards. In these cases the patella is completely dislocated on the outer condyle of the femur (*fig.* 6), because the tubercle of the tibia, in its movement of rotation outwards, carries with it the ligamentum

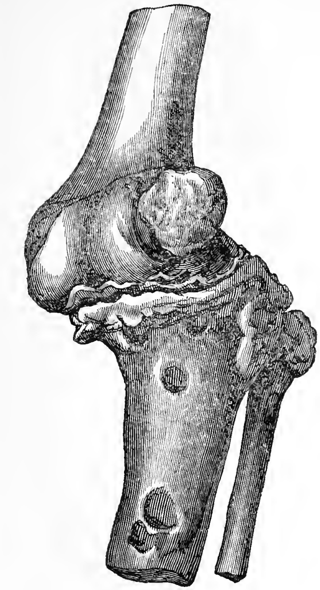
Partial displacement of femur inwards; tibia and patella outwards.

patellæ, and consequently gradually draws this bone outwards completely over the outer edge of the trochlea of the femur. We have seen at the Richmond Hospital two similar cases of this very curious result of necrosis of the tibia. In these examples the knee-joint had participated in the inflammation of the contiguous structure, and great deformity of the whole limb was the consequence (*fig.* 7). The subject of one of these cases (Christopher Tarrer, æt. 30) died of erysipelas, which was idiopathic, and had no connexion with the deformity. The knee-joint was examined, and the patella was found dislocated outwards, and anchylosed to the outer surface of the external condyle of the femur (*fig.* 8.) The superior extremity of the tibia was partially displaced backwards, and was greatly deformed and enlarged, particularly the outer condyle of this bone, the anterior half of which was deeply excavated to receive the condyle of the femur; the posterior half of this condyle was free and had no bone in contact with it; but this portion of the tibia and the head of the fibula were so much rotated or twisted outwards and backwards as to form a very conspicuous elevation in the lower part of the popliteal space. The fibula was placed directly behind the tibia. The lateral ligament did not exist. The ligamentum patellæ was greatly

Fig. 8.



Femur displaced inwards. Patella anchylosed.

Fig. 9.

Displacement backwards of the superior extremity of the lower fragment.

elongated and was directed backwards. The crucial ligaments were also elongated, and instead of crossing each other were untwisted as it were and lay side by side. The cartilages were altogether removed, and when the femur was forcibly separated from the tibia, there were corresponding elevations and depressions which marked the several points of contact between the bones, in which a species of anchylosis had occurred. The body of the tibia was greatly enlarged and hypertrophied, and round perforations existed in its head, from which sequestra had been discharged.

II. Abnormal conditions of the knee-joint resulting from accident.— Fractures and dislocations are the principal accidents to which the bones of the knee-joint are liable. The *muscular* and tendinous fibres common to the rectus, cruræus, and vasti are occasionally torn from the patella, and the ligament of this bone is also sometimes ruptured. The proper ligaments, too, and other structures of the knee-joint, suffer from sudden injuries, which we must here advert to as briefly as we can.

Fractures of the shaft of the femur near to the knee-joint may be *transverse* or *oblique*, or one or both of the condyles may be broken off from this joint.

1. When a *transverse* fracture is situate immediately above the condyles of the femur, it is the inferior fragment which is displaced, its superior extremity being directed backwards towards the popliteal space (see *fig*. 9); the anterior part of the condyles and trochlea have their aspect directed upwards, and form a swelling above the patella, giving to the joint a singular appearance. This direction backwards of the superior extremity of the lower fragment is the result of the action of the gastrocnemii, the plantaris, and popliteus muscles.

2. *Oblique fractures* of the lower extremity of the femur near the knee-joint are more serious and embarrassing than transverse fractures, not only on account of the immediate danger of the penetration of the skin by the upper fragment, and of the accident being thus rendered compound, but also on account of the great difficulty which is always experienced in maintaining the bones in apposition during the treatment of the case.

Sir A. Cooper says the appearances presented by the usual oblique fracture of the lower extremity of the femur are the following:—" The lower and broken extremity of the shaft of the femur projects, and forms a sharp point, which pierces the rectus muscle, just above the patella, threatens to tear the skin, and sometimes does so, whilst the patella, tibia, and condyles of the femur sink towards the ham, and are drawn upwards behind the broken extremity of the shaft of the os femoris, which is thrown forwards." He adds that falls from a great height on the feet or knees have been the usual sources of this accident.* In most of the cases already met with, and described, of oblique fracture of the lower extremity of the shaft of the femur, the direction of the obliquity was from above downwards, and from behind forwards, and the pointed extremity of the broken bone was consequently directed downwards and forwards; but the pointed extremity has been seen towards the popliteal space. In Sir Charles Bell's lectures on the thigh-bone which he has published, there is an engraving of a very remarkable case, which appears to us to have been an oblique facture of the femur near the knee-joint, in which the pointed extremity of the superior fragment presented towards the popliteal space.† About twenty years after the bone had been fractured, the patient, in jumping down from a chair, felt something snap, and very soon after a pulsating tumour formed, which was discovered to be a popliteal aneurism. The direction of the course of an oblique fracture may be various; that downwards and outwards is the least likely to be followed by dangerous consequences.

3. *Oblique fractures* of the os femoris into the knee-joint, detaching laterally the condyles, are not very uncommon accidents; they may be known by the great and sudden swelling of the joint by which they are accompanied, by the great degree of lateral motion which can be communicated to the limb, by the crepitus which can be felt, and by the obvious deformity with which they are attended.

It is sometimes the inner condyle, and sometimes the outer, which is detached from the shaft; and in these cases the cavity of the synovial membrane of the knee-joint is always opened into by the fracture. The following case presents a good example of an oblique simple fracture, which detached the outer condyle of the femur from the shaft of this bone.

Ganet Doyle, æt. 45, was admitted into the Richmond Hospital under the care of Dr. Hutton on the 27th March, 1839. He stated that about ten minutes before his admission he was standing on a double ladder about four feet from the ground; the ladder gave way under him suddenly, and he fell with it, the right limb having been engaged between two of the steps. During the fall he was sensible of being bruised below the knee by the steps, and of something "cringing" in the lower part of the thigh; immediately after the fall he found the limb quite powerless and was unable to put it under him. Tumefaction of the knee and lower part of the thigh took place instantly and to a great extent. On examination the outer condyle was found to move and grate against the inner through the centre of the joint; no breach of continuity could be detected between the inner condyle and shaft of the bone. The femur, as the patient endeavoured to stand, was directed downwards and inwards, and the tibia downwards and outwards, so that the junction of these two bones at the knee-joint formed an obtuse angle salient internally. There was considerable enlargement of the femur in the situation of the fracture for several inches above the knee-joint, and on measurement there was shortening of the injured limb for half an inch. By making extension, and by pressing the condyles towards each other, the natural form of the limb was restored. No fever nor constitutional disturbance arose, and at the end of the fifth week passive motion was recommended. When the man left the hospital the external appearance of the joint was very nearly natural, except that the patella had been elevated at its outer edge obliquely by the callus which had united the fracture. When this bone was moved across the trochlea of the femur, a roughness was perceived to exist on the corresponding surface, and a sensation of something grating was conveyed to the fingers of the examiner. There was some shortening of the limb, which also still remained more inclined inwards towards the knee-joint than natural, and the movement of flexion was limited.

Sometimes an oblique fracture occurs through the lower part of the femur into the joint, which detaches the inner condyle. The prognosis in these cases of simple oblique fractures of the inner and of the outer condyle of the femur, so far as life is concerned, does not appear, from what we have seen of them, unfavourable; but we have known some examples of what may be designated as T fractures of the lower extremity of the femur—that is to say, a transverse fracture of the lower extremity of this bone, combined with a vertical split from the transverse fracture down through the trochlea into the outer condyloid fossa of the femur, in which the prognosis is generally unfavourable, even when the fracture is uncombined with any wound in the integuments. Mr. Chelius, of Heidelberg, shewed Mr. Smith and the writer, in August 1837, two specimens of T fracture of the lower extremity of the femur. In the first case, the exact nature of the accident was unknown to Mr. Chelius. Violent inflammation set in in the knee-joint and the whole limb, causing the death of the patient. In the second case he recognized the nature of the injury early, and amputation in the thigh saved the patient In such cases, to decide at once whether amputation shall be immediately resorted to or not, becomes a very critical and often a very urgent question. If the first opportunity be lost, the constitutional symptoms attendant on the local inflammation set in so speedily, and run to such a height, that a second seldom offers; the two following examples, however, should caution us against deciding hastily on immediate amputation in cases of simple fracture, in which the cavity of the knee-joint is implicated, because, although in the first case the femur was broken into a great number of fragments, the inflammation

* Sir A. Cooper on Dislocations, 8th edition, plate xv.

† Fig. 3, plate iv.

which followed was inconsiderable, and in the second an opporiunity for "secondary amputation" was afforded even after acute inflammation of the joint had taken place.

A healthy labourer, about 30 years of age, was admitted into Jervis-street Hospital about eight years ago, under the care of the late Mr. Wallace, for a comminuted, but still a simple fracture of the lower extremity of the femur, where it entered into the formation of the knee-joint. The accident was attended with enormous effusion, and there was a degree of mobility of the limb in the seat of the comminuted fracture truly astonishing; but little inflammation followed, and under the simplest treatment the man ultimately recovered with a stiff knee-joint. The second case was that of a boy aged 13 years, who had received a simple fracture of the lowest part of the shaft of the femur. The condyles of this bone were detached at their normal line of junction with the shaft, and where they are covered with synovial membrane; the posterior and anterior crucial ligaments were separated from the femur, and had carried with them small portions of this bone. The result of the operation is not recorded, but the specimen, preserved in our museum at the Richmond School of Medicine, exhibits, besides the injury the bones received, traces of the very acute inflammation which followed, particularly on the surface of the synovial membrane, which is covered with lymph. The periosteum of the femur in the vicinity of the fracture is much thickened and detached all round from the femur.

Among the valuable preparations presented by Mr. Kirby to the College of Surgeons in Dublin is a specimen of one of these transverse fractures of the lower extremity of the femur, which was combined with a vertical split of the bone down through the trochlea and outer condyloid fossa. Although the fracture was a simple one, it was followed by enormous effusion, succeeded by acute inflammation of the structures of the joint; and Mr. Kirby informs me that amputation was successfully resorted to. The synovial membrane was much thickened, and evidences of acute inflammation of the structures of the knee-joint are still to be seen in the preparation.

Fractures of the tibia close to the knee-joint may be *transverse*, or through the line of junction of the epiphysis with the rest of the tibia in the young subject, or in the situation and direction of this line in the adult. In this case the broad surfaces of the broken tibia nearly maintain their relations with each other. If there be any displacement, it will be that of the superior fragment, which will be drawn backwards towards the popliteal space, as the inner hamstring muscles will draw the bone in this direction.

Oblique fractures of the upper extremity of the tibia which run into the knee-joint are accompanied with symptoms not very dissimilar from those belonging to oblique fractures of the internal condyle of the femur, except the situation of the pain, and the crepitus which can be elicited on motion being communicated to the broken portion of bone. There is the same sudden effusion into the knee-joint, and a very great degree of lateral motion is allowed, which is a movement the knee-joint does not normally possess.

We learn from Blandin that Beclard had very frequently observed elderly females to be the subjects cf fractures of the upper portion of the tibia, produced by the contraction of the flexor muscles of the leg, which muscles also he observed uniformly pulled the superior fragment into the hollow of the ham. The explanation of the fracture occurring from such a cause must be referred to the atrophy which the head of the tibia undergoes in elderly people, in consequence of which the tibia becomes thin in its shell, and the interior osseous structure reduced to a thin reticular tissue, which in the dead subject we notice to yield to the slightest pressure of the fingers. We have known this atrophy of the tibia to exist in adults as well as in old subjects, and when present, it of course renders the bone liable to be broken by slight causes. Moreover, we have usually found the species of reunion of the broken bone which can be effected under such circumstances to have been very imperfect; the patient after a long period endeavours to move about with the assistance of crutches; and effusion takes place into the knee-joint, the functions of which become greatly impaired for the rest of life.

Fracture of the patella.—This fracture occurs almost always in the transverse direction; it is rarely oblique, and still more rarely longitudinal; sometimes a fracture divides this bone into three or four pieces, or is what is called comminuted. The longitudinal fracture is rare, and this and the comminuted are generally the result of direct violence; and, although the transverse fracture may depend on a similar cause, still the violent contraction of the extensor muscles of the leg is the most frequent source of this accident. When a fall occurs directly on the front of the knee, this joint being at the moment in a state of semiflexion, if a fracture take place it will no doubt be considered as the result of the fall directly on the bone, by which it is broken; certainly muscular action may lend its assistance to the external violence even in producing the fracture, and *after* this has occurred, to cause the separation of the fragments.

This fracture cannot so readily be effected by muscular action when the limb is in a state of complete extension as when it is in a commencing state of flexion, because in complete extension the muscles act in the direction of the long axis of the bone; but in flexion at the knee to the first degree the patella is in a particular condition, which is favourable to the production of fracture; it only applies itself to the condyles of the femur by its middle point. The base and summit of this bone are unsupported; the extensor muscles of the leg on one side, and the tendon or ligament of the patella on the other, are, in this position of the joint, oblique with relation to the long axis of the patella; the muscles then bend the patella backwards, and it breaks transversely, —according to Boyer and Malgaigne, "par la même mecanisme que nous cassons un bâton placé en travers le genou ; en agissant avec les deux mains sur ses deux extremités." In transverse, oblique, and comminuted fractures of the patella there is almost always more or less separation of the fragments, and the signs of the accident are easily recognized. In some cases of fracture of the patella the fibrous and aponeurotic layer which immediately invests it anteriorly is broken ; in other cases, particularly those from external violence, the fibrous layer remains entire; it is in these latter cases, as the fragments are preserved in complete apposition, that bony consolidation may be expected. The following case, which it lately fell to our lot to attend in the Richmond Hospital, appears to possess some interest as a fact, tending to throw light on some of the disputed questions here adverted to relative to this accident.

A man, æt. 18, on the evening of 16th February, 1839, fell from the height of twenty feet to the ground, and fractured two of the cervical vertebræ, of which injury and its consequences on the spinal marrow he died in forty hours. His lower limbs were paralyzed. It was noticed that the integuments over the patella were much bruised, and that there was some effusion into the cavity of the knee-joint. On the post-mortem investigation, the patella was found traversed by a perfect fracture of the bone; but the fragments were not separated from each other. On examining the patella anteriorly, its fibrous and aponeurotic coverings were in a perfect condition. Upon looking at the posterior articular surface of the patella, the *cartilage* was broken corresponding to the line of the transverse fracture of the patella, but only half-way across the transverse extent of the fracture was entirely through the bone. We regarded this accident to the patella to be the result of direct violence, complete paralysis of the lower limb having occurred as the immediate effect of the lesion of the spinal marrow; the usual source of displacement arising from muscular contraction was here destroyed. When we bear in mind the complete apposition existing in the fragments of this patella, we cannot for our parts question but that if life had been preserved, complete consolidation should have taken place. Although but few doubts are now entertained that the transverse fracture of the patella is in general a real rupture of the bone transversely, owing to the powerful action of muscles, it may not perhaps be amiss to adduce as an example of it, the following case of a patient who many years ago was under the care of the late Mr. Todd in the Richmond Hospital. A remarkably muscular man, a lamp-lighter in this city (Dublin), was on the top of his ladder when it slipped from the lamp-post, and he fell with it to the ground, making at the moment vain but violent efforts to save himself. The whole muscular system, according to his own account, seemed to be suddenly thrown into energetic and involuntary effort, to resist the fall; when he was lifted up, he was unable to stand. Mr. Todd, having examined him, found both olecrana and both patellæ broken transversely. We have often heard the above-named professor mention this case in his lectures, and the treatment of the accident was also witnessed by Dr. Hutton.

It was for a long time greatly doubted that bony union of the broken pieces of the patella could occur, but it is now fully proved that the fractured patella does not want really any of the conditions necessary to the reunion and consolidation of broken bones. The spongy structure of the patella and the great number of bloodvessels entering into its structure ought to favour the inflammatory turgescence (Boyer) which seems necessary in the early stage of ossification, and would do so but that the continual contraction of the muscles feebly resisted by the bandages suggested by surgery, keeps the fragments separated from each other, and hence union has been so rare in those cases that the possibility of it under any circumstances was for a long time questioned. Pibrac, one of the most distinguished members of the ancient Academy of Surgery of France, defied all the surgeons of Europe to shew a specimen of the fracture of the patella united solidly by bone, and no example was at that time produced. Among many cases published since that time in various works, proving the possibility of bony consolidation of the broken patella, we adduce the following.*

Louis Manilla, aged 36 years, of a most vigorous constitution, being a veteran soldier in the Salpetrière, on the 7th of April, 1797, was thrown down by a comrade, with whom he was struggling. One of his knees supported all the effect of this fall, and the patient suffered in this part a sensation of crackling and laceration, and a pain which was extremely severe. He could not rise without assistance, and M. Lallement recognised a transverse fracture of the patella. The interval between the two fragments was very perceptible, but approximation of the two pieces was easily accomplished when the leg was extended. The patient having been brought to the infirmary, the fracture was reduced by M. Lallement, and retained by means of the apparatus of Desault. This bandage was kept on for two months, at the end of which time the fracture appeared to be united. During one year the patient walked with the assistance of a cane and then returned to his duty. The movements of the knee were nearly perfect, with the exception of flexion of the leg, which was still a little confined on the 18th Aug. 1810. Manilla died of an attack of apoplexy, and M. Lallement having examined the knee became satisfied that the two fragments of the patella were solidly united. This bone being submitted to ebullition for ten hours was deprived of the articular cartilage which covered its posterior surface, and of the tendinous and aponeurotic fibres which enveloped it. It was now evident that the total height of the patella

* See Boyer's Surgery, vol. iii. p. 358. Edit. *Paris,* 1818.

which had been broken exceeded by about six times the same diameter of that of the opposite side. The fracture did not represent a straight transverse line, but was somewhat undulated. At the two extremities of the line of junction of the fracture it was quite evident that the union of the broken bone was immediate, and by the intervention of a true bony callus. Lallement presented Boyer with the patella thus solidly united, and he has given an engraving of it in his valuable work.

In the collection of Dr. William Hunter, there is a well-marked instance of bony union of a transverse fracture of the patella, and other examples have been seen in the dead subject by Mr. Wilson. In Sir Charles Bell's museum were likewise similar specimens, one or two of which are now in the Museum of University College.*

Dislocations of the femur from the tibia at the knee-joint.—The articular surfaces of the head of the tibia for the reception of the femoral condyles are very superficial; and although the semilunar cartilages are superadded to them for the reception of the condyles of the femur, they have no direct tendency to resist luxations of the femur at the knee-joint. On the other hand it is to be recollected that the surfaces by which the tibia and femur are articulated together are broad, and that the number and strength of the ligaments which unite these bones is considerable. The solidity of the articulation is further augmented by numerous and powerful tendons which surround the joint. Although therefore the knee-joint from its situation and functions must be subjected to numerous injuries, dislocations are very seldom witnessed as the result of accident. Dislocations, however, occur in four different directions; two of them are incomplete and lateral while the others are perfect luxations, the femur being thrown either backwards or forwards. The lateral luxations are the rarest.

The lower extremity of the femur is now and then dislocated *backwards:* the *signs* of the accident are the following. The thigh-bone is somewhat displaced to the side as well as backwards, and the tibia is advanced before the condyles of the femur. The lower dislocated extremity of the os femoris makes such pressure on the popliteal artery as to prevent the pulsation of the anterior tibial artery on the foot. The patella and tibia are drawn by the rectus muscle forwards; such, Sir A. Cooper tells us, are the appearances the knee-joint presented in a man brought into St. George's Hospital in the year 1802. The limb in this case was easily reduced by extending the thigh from above the knee, and by drawing the leg from the thigh and inclining the tibia a little backwards. As soon as it was reduced, the popliteal artery ceased to be compressed, and the pulsation in the anterior tibial artery was restored. We will quote the following abstract of a case of dislocation of the lower extremity of the femur backwards;† the subject of the accident, besides other injuries, was brought into the Chester Infirmary with a very complete dislocation of the lower extremity of the femur backwards. The whole limb was shortened four or five inches, and the condyles of the femur could be felt plainly among the muscles of the calf of the leg, while the tibia was in advance of the femur and drawn upwards on the anterior part of this bone. The leg and foot were swollen and cold; all circulation below the knee was stopped; there were no marks of external contusion. It appears that although the pulleys were used to reduce the luxation, it was easily effected by gradual extension of the limb. It became necessary after about five weeks had passed from the time of the accident, to amputate the limb in consequence of an extensive abscess which formed in the ham and calf of the leg. Upon examining the amputated limb, it was found that the popliteal abscess was very extensive and communicated with the knee-joint. On tracing the course of the artery, which had been previously injected, it was found to be obliterated from just below the point where it gives off the superior articular artery, exactly to its bifurcation into the anterior and posterior tibial arteries. The nerve also for this distance was slightly enlarged and firmer than natural, having a cord-like feel; the whole being so closely connected by dense cellular tissue as to be scarcely separable. The attachments of the muscles were all perfect and did not appear to have been lacerated. With respect to the joint the lateral ligaments on both sides were perfect; the anterior crucial ligament had been absorbed, but the posterior crucial ligament and the posterior ligament of Winslow were united into one band; the synovial membrane was healthy or but very little altered; the semilunar cartilages, as well as those on the ends of the bones, were sound; there was no fluid in the joint.

Case of dislocation of the femur backwards from the tibia.—Sir A. Cooper remarks that cases of dislocation of the knee-joint are so rare that every instance of this accident is worthy of recital. He adduces the following example from the experience of Mr. Toogood, of Bridgewater. Francis Newton, a strong athletic man thirty years old, fell from the fore part of a waggon, and was dragged a great distance before he was disentangled from the framework of the shafts. In two hours after the accident the left knee was observed to be very much swollen; the os femoris was dislocated backwards, and its lower extremity occupied the upper part of the calf of the leg, the internal condyle of the femur being nearly through the skin; the tibia, fibula, and patella were driven up in front of the thigh. The appearances of the limb were so dreadful that Mr. Toogood despaired at first sight of being able to reduce it, but to his surprise the reduction was easy. The limb was placed in splints; the strictest antiphlogistic treatment with rest was prescribed; the symptoms were mild, and he suffered little from pain or inflammation.

Malgaigne, in a letter to Velpeau in the Archives Medicales, June 1837, upon the subject

* Prof. Cooper.

† London Medical Gazette, May 14, 1836, given by Mr. Thomas Brittan, House Surgeon, Chester Infirmary.

of dislocation of the knee, to which we refer for many observations we have not space for, gives a case of luxation of the femur backwards and of the tibia forward, which in some respects differed from those adverted to by Sir A. Cooper. He informs us that M. Lavalette was called on the 6th of April, 1815, to visit a man who had just before met with the accident we are now describing under the denomination of dislocation of the femur backwards and of the tibia forwards at the knee-joint. The limb was in a state of extension, somewhat inverted, and much shortened; it could, however, be flexed and extended, although with much pain. The extensor muscles of the leg were in a relaxed condition, as were also the hamstring muscles from the shortening of the whole limb. A depression existed where the condyles of the femur ought to present themselves anteriorly, and below this space the superior extremity of the condyles of the tibia could be felt. The patella was placed horizontally on the upper articular surface of these condyles; its point, which is normally placed downwards, was now directed forwards, and its superior margin backwards; its anterior or cutaneous surface was placed directly upwards, and its articular facet downwards, resting, as already mentioned, on the flat surface of the upper extremity of the condyles of the tibia. Lavalette here knew that he had to deal with a complete luxation, which we have called a luxation of the femur backwards and of the tibia forwards; and he was finally convinced of the real nature of the case by placing his hand in the popliteal region, where he distinctly felt the two condyles of the femur.

Luxation of the lower extremity of the femur forward.—The lower extremity of the femur is sometimes thrown *forwards* off the condyles of the tibia, while the latter bone is thrown backwards behind the condyles of the femur, producing the following appearances: the limb is shortened, the condyles of the os femoris are seen projecting, the ligament of the patella is depressed, and the leg is bent forwards. Sir A. Cooper gives a case in which the condyles of the femur were completely dislocated *forwards*, and the head of the tibia passed so far backwards behind the condyles as to fill up completely the popliteal space. The tendinous connexion of the patella to the rectus muscle was ruptured; the external condyle of the os femoris was very protuberant; the leg was bent forward and shortened, and a depression existed just above the patella. The patient felt most excruciating pain when the limb was moved, but when at rest there was not any considerable suffering; the luxation was reduced, and in five months recovery was complete.

Lateral luxation of the femur at the knee-joint.—Although from the structure of the parts it might at first be supposed that complete lateral luxation should be less resisted than the luxation of the femur either forwards or backwards, still there is no case on record with which we are acquainted of complete lateral luxation of the femur from the tibia as the result of accident. We commonly see only one of the condyles of the femur abandon the tibia, while the other remains in the cavity the first had left. The luxation is then what is called incomplete. The reduction of this luxation is easy in consequence of the rupture of the ligaments.*

Dislocation outwards of the femur at the knee-joint.—In the dislocation outwards of the femur at the knee-joint, this bone is thrown off the external condyle of the tibia, and this latter bone projects on the inner side of the joint so as at once to disclose the nature of the injury. Sir A. Cooper once saw a case of this kind at St. Thomas's Hospital, and stated he was struck with three circumstances. The first was the great deformity of the knee from the projection of the tibia inwards; the second, the ease with which the bone was reduced by gradual extension; and the third, the little inflammation which followed upon what appeared so serious an injury. The man was discharged after a few weeks, having suffered little local or constitutional irritation.

Example of dislocation of the femur outwards.—Mr. Bovill was thrown from a gig; the femur projected much externally at the knee, and the tibia much (below the situation of the inner condyle of the femur) to the inner side of the condyle of the os femoris. The limb was extended from the thigh-bone, in a bent position; the extension was a long time continued, and force was employed by several persons for half an hour before the luxation was reduced. Sir A. Cooper saw him eighteen months after the accident; the patient could not then bend the limb at right angles with the thigh; there was also an unnatural lateral motion of the joint from the injury which the ligaments had sustained.

Incomplete dislocation of the femur inwards at the knee-joint.—The femur is sometimes thrown on the *inner* side of the knee-joint, the condyles of the tibia being carried outwards. The under surface of the inner condyle of the femur may be felt through the skin, while the outer condyle of this bone rests on the cup-like cavity hollowed on the upper extremity of the inner condyle of the tibia, or rather behind it. A deformity is produced analogous to that in the external dislocation, and may be easily conceived. From the little experience had of such cases, the reduction of the limb is stated to be equally easy with the former, and the patient recovers with little diminution of the powers of the part. Sir A. Cooper states as his opinion that in these cases the condyle of the os femoris with respect to the tibia is thrown somewhat backwards as well as outwards or inwards. An alderman fell from his horse and partially dislocated the condyle of the os femoris inwards, and the tibia outwards; the femur was easily replaced. He was perfectly recovered in twelve months.

To whichever side the tibia is luxated, it always pulls with it the patella, which suffers

* Blandin says: "Je l'ai eprouvé moi-même une fois à l'Hôpital de la Charité." Traité d'Anat. Topog. Paris, 1826, p. 617.

also a displacement more or less considerable according to the degree of displacement of the tibia. In these incomplete dislocations of the knee-joint, the patella, it is said, suffers but little displacement, its long axis only becoming oblique, and the lower point of the patella being directed either outwards or inwards, towards the tubercle of the tibia, according to the nature and direction of the dislocation. These are the opinions of Boyer, who evidently has not witnessed many cases of either complete or incomplete dislocations of the knee-joint. From what we ourselves have noticed of the situation the patella takes when the bones are displaced under the influence of disease, we should be disposed to believe that even in partial luxation of these bones laterally—particularly in the dislocation of the femur inwards and of the tibia outwards—in *this* case the patella would be thrown completely over the trochlea and lie on the outer side of the external condyle, as in *fig.* 6 and 8. If the limb be flexed and at the same time the tibia everted, such an event appears almost inevitable.

Dislocations of the patella.—Although the patella is not articulated with the tibia, nevertheless it is so strongly attached to this bone by ligament that the leg cannot be luxated from the femur without the patella necessarily undergoing a change of place; but the patella may be luxated independently of the tibia. Authors speak of luxations of the patella in the directions upwards, downwards, inwards, and outwards; but of these the two last alone deserve the name of luxations. The patella cannot descend beneath its usual place unless the extensor muscles of the leg be torn from their attachment to its upper margin; nor can this bone be elevated above its usual situation unless the ligamentum patellæ be ruptured. Luxations of the patella then may take place in the direction inwards or outwards. The latter is decidedly the more common. Either luxation may be complete or incomplete. (*Boyer.*)

Complete luxation of the patella outwards.—In this accident the patella is thrown completely off the articular trochlea of the femur. The internal edge of the bone is directed forwards, its external edge backwards; its posterior cartilaginous surface is applied to the outer surface of the external condyle of the os femoris, and its anterior or subcutaneous surface is turned completely outwards. In this case the ligamentum patellæ is somewhat twisted on itself, and its direction rendered oblique.

We recognize the complete luxation outwards by the extended condition of the patient's limb, by his inability to flex it, by the severity of the pain when he attempts to do so, and by the depression which is observed to exist in the place the patella had abandoned, (at the bottom of which depression we can easily distinguish the articular pulley of the femur); finally, by the tumour formed by the patella on the anterior part of the tuberosity of the external condyle of this bone. The accident usually occurs to a person who, while walking or running, falls with the knee turned inwards and foot outwards, and thus by the violent action of the extensor muscles instinctively exerted to prevent the fall the patella is drawn over the external condyle of the os femoris. When the person rises he finds himself unable to bend or extend his leg, and the muscles and ligaments of the patella are on the stretch. This accident is generally the effect of muscular action, but the dislocation may result from accidental force acting on the patella.

In the greatest possible flexion of the leg the patella is too much sunk between the condyles of the femur, and is too strongly applied against these eminences by its ligament and by the tendon of the extensor muscles, to permit it to yield to the action of external force. But, on the contrary, when the leg is moderately extended, these attachments are relaxed; the bone projects more, and enjoys greater mobility, which renders it susceptible of yielding and of being displaced either outwards or inwards according to the direction of the impelling force. The luxation outwards, more easy and more frequent than that inwards, is ordinarily, as we have stated, the effect of a force acting upon the internal edge of the patella, by which this bone is pushed outwards, the leg being at the time either extended or moderately flexed. The natural prominence of the internal border of the patella renders it liable to be acted upon by blows, &c., and to be from this cause frequently thrown outwards over the external condyle of the femur.

The patella is sometimes dislocated spontaneously in persons of weak habit and of lax fibre, as it is denominated. If a person of this constitution be so malformed that the knees are directed too much inwards, the patellæ are from this cause still more predisposed to spontaneous luxation. The mere circumstance of the existence of a faulty inclination of the knees inwards is not sufficient in itself to predispose a patient strongly to a dislocation of the patella outwards; but when such a malformation coincides with an habitual state of muscular relaxation, this spontaneous luxation is likely to occur.

Luxation of the patella inwards.—This luxation is much less frequent than that outwards. It happens from falls against a projecting body, by which the patella is struck upon its outer side, the leg being at the time of the fall turned inwards. We require no other signs to enable us to recognize this accident than the cavity we notice in the place the bone has left, and the eminence it forms in the place to which it has been transferred, namely, on the internal side of the inner condyle of the femur.

Incomplete luxation of the patella.—The signs of this incomplete luxation are so evident* that it is impossible to mistake them. The leg is extended, and if we endeavour to flex it, the pain the patient suffers is considerably increased. The natural form of the knee is altered; we perceive through the skin the

* Boyer.

salient internal border of the articular pulley of the femur, which the patella has abandoned. This last bone forms in front of the external border of the pulley a very remarkable tumour, upon which the finger may easily distinguish the external border of the patella. We can also easily recognize through the skin and the capsular ligament the posterior articular surface of the patella, which has passed beyond the edge of the trochlea of the femur.

"In the course of a long practice," says Boyer, "I have met with but one case of dislocation of the patella," (and this, it appears, was an incomplete luxation.) "A young man, æt. 16 to 18, very tall, fell, running along a corridor. The internal part of the knee in passing struck violently against the corner of a trunk, which produced an incomplete luxation of the patella outwards. The surgeon in ordinary of the family was called; but whether it was that he did not recognize the luxation or that he did not consider he could reduce it, he did not wish to undertake it without having the assistance of Sabatier. This celebrated professor was at first uncertain as to the species of dislocation which the patella had suffered; but having carefully examined it and reflected on the phenomena the accident presented, he recognized the true nature of the case. He then attempted the reduction of the luxation, but failed in replacing the bone."

When Boyer arrived, he states that the patient was lying on his bed, the limb being extended and raised by pillows. The ordinary form of the knee was altered; the patella formed a tumour, which was sensible on the front of the external border of the articular pulley of the femur; in front of the internal border of the same pulley there was a depression, in the bottom of which could be perceived with the finger the same border of this pulley. The direction of the patella was changed in such a manner that its anterior surface was inclined inwards, and its external border forwards; finally, the external articular facet of the patella could be felt by the touch through the integuments which covered it. By these signs it was easy to recognize the incomplete luxation outwards.

Luxation of the patella on its edge.—Some very eminent surgeons have doubted the possibility of such an occurrence as a dislocation of the patella on its edge. "Some," says Boyer, "have imagined that the patella could be luxated turning half round on its vertical or long axis so as to rest on one of its edges on the articular trochlea of the femur. We cannot conceive," he proceeds, "how the tendon of the extensor muscles of the leg and the ligament of the patella could lend themselves to such a rotation of the bone on its long axis; much less can we understand how these parts can admit of a total reversion of the bone, as authors pretend to have observed." Notwithstanding these observations, it seems fully proved, that the patella can really be dislocated on its edge, and if we once admit the possibility of the partial rotation of the bone on its long axis, so as to constitute what is called a dislocation of the patella on its edge, we can imagine that a more complete rotation of the bone on its long axis might happen, constituting the complete reversion of the position of the surfaces and edges of this bone spoken of by some writers.

It does not appear that Sir A. Cooper has seen the dislocation of the patella on its edge, but he states that he was informed by Mr. Willing, formerly of Hastings, that he was called to a case in which the patella was dislocated on its edge. The nature of the accident was very obvious, as the edge of the bone forced up the integuments to a considerable height between the condyles on the fore part of the joint. Mr. Willing reduced the dislocation, but with considerable difficulty, by pressing the edges of the bone in opposite directions.

The following case of dislocation of the patella on one of its edges occurred lately in the practice of Mr. Pentland, surgeon to the Drogheda Infirmary, and is very interesting and important, coming as it does from an acute and experienced observer. J. M'Greene, æt. 25, of middle stature, was struggling to get down a strong man in play. He succeeded so far as to get him on his knees, when the fallen man took hold of both his legs with his arms closely embraced round them, and when M'Greene was struggling to disengage himself, he heard and felt his right knee give a loud snap. This was attended with the most excruciating pain, and he fell to the ground to the left side; he felt that he had lost all power over the right leg. He was carried to bed, and Mr. Pentland saw him in a few minutes after the accident. The knee was in a flexed state, presenting a most extraordinary appearance, but which was readily seen to proceed from the patella having been dislocated on its edge. Mr. Pentland stated that he had some difficulty in ascertaining which side was turned out, but he soon concluded that it was the under or articular surface. The man could not move the limb at all, "and never," says Mr. Pentland, "did I witness more dreadful suffering. You would suppose," he adds, "that the patella would force out through the integuments." After repeated attempts he at length succeeded in getting it into its place; the reduction was attended with a loud noise, and during the operation the man seemed to suffer frightful torture. Immediately on the reduction, all pain ceased, and in a very short time he recovered the perfect use of the limb.

A case of dislocation of the patella on its edge is recorded by Dr. Watson in the New York Journal of Medicine and Surgery, October, 1839. He calls the accident a dislocation of the patella on its axis, and says, "in the case I have described, the leg could be slightly flexed; no part of the pulley except its elevated border at the condyles of the femur could be felt. The patella was drawn upwards, and twisted nearly at right angles with its proper position, so that its anterior face was directed inwards, and its outer edge was thrown completely forwards, forming an uneven and very prominent line beneath the skin in front of the joint. The reduction of the bone to its normal position was not effected without difficulty."

Internal derangement of the knee.—" The knee-joint," says Mr. Hey, " is not unfrequently affected with an internal derangement of its component parts, and this sometimes in consequence of trifling accidents. The defect is, indeed, now and then removed as suddenly as it is produced, by the natural motions of the joint without surgical assistance; but it may remain for weeks or months, and will then become a serious misfortune, as a considerable degree of lameness may remain. This disorder may happen either with or without contusion. In the latter case the accident is easily distinguished from all others. The joint, with respect to external form, seems perfect; if there be any difference from its natural appearance, it is, that the ligament of the patella appears rather more relaxed than in the sound limb. The leg is readily bent and extended by the hands of the surgeon, and without pain to the patient; at most the degree of uneasiness caused by this flexion and extension is trifling; but the patient himself cannot freely bend, or perfectly extend the limb in walking; he is compelled to walk with an invariable and small degree of flexion. Though the patient is obliged to keep the leg thus stiff in walking, yet in sitting down the affected joint will move like the other."

The complaint, Mr. Hey apprehends, may be brought on by any such alteration in the state of the joint as will prevent the condyles of the os femoris from moving truly in the hollow formed by the semilunar cartilages and articular depressions of the tibia. According to him, an unequal tension of the lateral or cross ligaments of the joint, or some slight derangement of the semilunar cartilages, may probably be sufficient to predispose any one to this accident. Sir A Cooper, in alluding to the internal derangement of the knee-joint described by Hey, calls the accident a " partial luxation of the thigh-bone from the semilunar cartilages;" but it does not appear to us that he had any opportunity of ascertaining the anatomy of such an accident. Sir A. Cooper has observed it to occur most frequently, when a person in walking strikes his toe, the foot being at the time *everted*, against any projecting body, as the fold of a carpet, after which the patient feels pain in the knee, which cannot be extended. He has also seen this accident happen from a person having suddenly turned in his bed, when, the clothes not suffering the foot to turn with the body, the thigh-bone has slipped from its semilunar cartilage. He also states that he has known it occur from a sudden twist of the knee inwards when the foot was turned out. He says, " under extreme degrees of relaxation, or in cases in which there has been increased secretion into the joint, the ligaments become so much lengthened as to allow the cartilages to glide upon the surface of the tibia, and particularly when pressure is made by the thigh-bone on the edge of the cartilage. The cartilages which receive the condyles of the os femoris are united to the tibia by ligaments; and when these ligaments become extremely relaxed and elongated, the cartilages are easily pushed from their situations by the condyles of the os femoris, which are then brought into contact with the head of the tibia; and when the limb is attempted to be extended, the edges of the semilunar cartilages prevent it." It may be inferred from his observations that the accident may occur either at the internal condyle, which is the more common, or at the external, and that the position of the foot at the time of the occurrence of the accident has much influence in determining which of the semilunar cartilages is to be displaced. Thus, if the toe be everted, the displacement of the internal cartilage will occur; on the contrary, if the foot be fixed and inverted at the moment of the accident, the subluxation of the external condyle of the femur from the external semilunar cartilage will be the accident. Sir A. Cooper adduces the following case. Mr. Henry Dobley, æt. 37, has often dislocated his knee, turning the foot inwards, and the thigh-bone outwards, by accidentally slipping on uneven ground, or by sudden exertions of the limb. Considerable pain was immediately produced, accompanied with a great deal of swelling. His mode of reducing it is as follows. He sits upon the ground, and then bending the thigh inwards, and pulling the foot outwards, the subluxation of the os femoris being external, the natural position of the limb becomes restored.

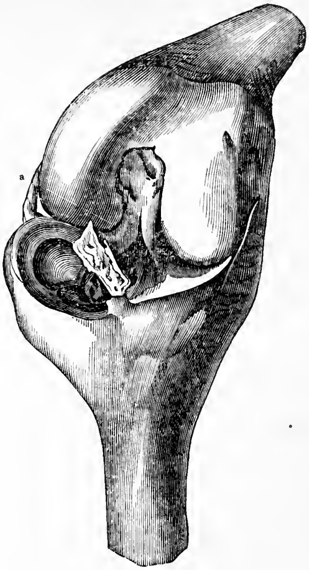
Mr. L. a well-formed gentleman, æt. 29, has consulted me twice or thrice these last two years concerning this internal derangement of the knee-joint so well described by Hey. Mr. L. complains that, whenever he unguardedly flexes the knee suddenly, the toe at the time being much inverted, he is instantaneously seized with very disagreeable sensations in the knee-joint, not amounting to pain. There is a sudden sense of weakness across the front of the joint, the limb is semiflexed, and a great feeling of tightness and stiffness exists behind, along the course and about the insertion of the biceps tendon. All these symptoms come on suddenly from some awkward movement or false step, such as, in walking, putting his foot into some unexpected hole, but so very suddenly does the internal derangement occur, that, if walking at the moment, he generally falls to the ground. After a little time, though lame, he is able to walk, and to place the heel to the ground, and though he usually keeps the limb slightly flexed, he can at will extend it. These accidents are usually followed by some effusion of synovial fluid into the joint. I have practised with success the extension and sudden flexion of the limb advised by Hey, and my patient has himself occasionally, and with success, directed this manœuvre to be practised on him by his servant, or by any one who happened to be at hand when the accident occurred. He attributes the first cause of this liability to the sudden derangement of the articulation to a violent sprain of the knee-joint he got while ringing a young and powerful horse; the latter pulled away from him with such violence, that Mr. L. fell to the ground, and during the fall he felt as if something at the internal side of the knee-joint had been broken: the thigh and tibia were bent in such a manner as to form an obstuse angle internally, and it is not improbable, that by the sprain the internal lateral ligament or other structures in the interior of the joint were injured. The sprain was followed by swelling, &c., and it was six weeks before he recovered so as to be able to walk. Mr. L. remained well for eight months, when, in crossing over a ditch, the sudden derangement recurred. The moment the displacement of some part of the interior of the joint occurred, he dropped suddenly to the ground. Another day, while practising some gymnastic exercise, it occurred. Again, it happened while in bed, the bed-clothes embarrassing the motion of the foot while he was turning his body round. On the last occasion on which the displacement happened, he was on horseback; he had just mounted, and was, while his knee was flexed, seeking with the *inverted* foot for the off-stirrup, when the displacement happened. On all these occasions he has without loss of time sought to replace the deranged parts, and sometimes has succeeded instantaneously, and sometimes weeks have passed without the adjustment of the parts in the interior of the joint occurring. The restoration of the use of the joint has always been as sudden as the derangement, and the replacement has invariably been accompanied by a sudden snap, as if something at that moment changed its place, and this to him was always the signal of recovery of the uses of the joint. When the extension and flexion of the limb in the manner recommended by Hey has been the means of restoration, he has on some occasions not only felt the sudden movement of what he considers the dislocated part in the interior of the joint, but he thinks he could distinctly hear the crack the part gave in resuming its ordinary place. The writer of this has lately seen and examined Mr. L.'s knee-joint, and compared it with the opposite one, and cannot perceive the slightest difference on a simple inspection of both articulations either before or behind. The patella and the ligament which connects it to the tibia are just as firmly applied in front of the joint as usual, and there is now no effusion into the joint of any unnatural quantity of synovial fluid. He habitually wears a laced knee-cap, and finds only a difficulty in flexing as fully the affected knee-joint as the other, and he has an habitual fear of any movement of the leg in which this is at the same time flexed, and the foot inverted. This is a well-marked example of the internal derangement of the knee described by Hey; but what are the true anatomical characters of the accident, or what really is the structure, whether normal or abnormal, which slips in and out with a noise? Nothing positive, in our opinion, has been added to the knowledge of the nature of the accident given to us by Hey, who has the merit not only of first describing the injury, but of also pointing out a simple and generally successful remedy.

Many surgeons have considered that the internal derangement of the knee described by Hey, and considered by Sir A. Cooper as a "partial luxation of the femur from the semilunar cartilages," is a dislocation of these fibro-cartilages. Malgaigne justly criticises the vagueness of the language used by authors relative to this matter. M. Velpeau, according to Malgaigne, in one place treats of this luxation as a luxation of the semilunar fibro-cartilages, and in another work he seems so uncertain of the nature of the accident as to demand whether the phenomena may not be owing to the existence, in the interior of the joint, of some of those cartilages which we call foreign bodies. Malgaigne himself seems to fall into the opinion of Sir A. Cooper upon this subject, although he does not use the same terms, and considers the accident to be a simple and partial luxation of the femur from the tibia, the consequence of the *relaxation of all the ligaments*, but adduces no anatomical evidence of the truth of his hypothesis. He considers the accident, " Une simple luxation incomplete du femur sur le tibia, produite par un relâchement de tous les ligamens, et tout-à-fait analogue aux deplacemens occasionés par la même cause dans les autres articulations." Sir A. Cooper is of opinion that Mr. Hey's plan is generally, but not invariably successful, and adduces the case of a lieutenant in the army who suffered this accident repeatedly, and the limb was often reduced by the above-mentioned means; but at length, turning in bed, from the pressure of the bed-clothes on his foot, the accident recurred. He came to London, but bending the limb had now no effect in enabling him to extend the joint. Sir A. Cooper, therefore, advised him to visit Mr. Hey, but he learned that in this case the dislocation was never reduced. In an obstinate case of this internal derangement of the knee-joint, which resisted all the ordinary means of surgical treatment, the writer succeeded (in Jervis-street Hospital) by using the pulleys. Under exactly similar circumstances, his lamented friend, Dr. M'Dowel, subsequently succeeded by having recourse to the pulleys when all other means had failed.

The knee-joint is seldom affected by *sprains*. When, however, there is an undue inclination of the knee inwards, the internal lateral ligament is occasionally, by an accidental false step or twist, sprained, and sudden lameness comes on followed by swelling, and more or less inflammation of the synovial membrane of the articulation. It has not been ascertained whether in such cases the fibres of the internal lateral ligament have given way, or whether they are detached from the bone or not; but it is not improbable that some such lesion has occurred as that we have already noticed under the head of *Sprains* in another articulation: (see Ankle.) When sprains of the knee take place, it is almost invariably the inner side of the joint to which the patient refers as the principal seat of tenderness and pain. The joint admitting of motion unaccompanied by any crepitation (although the act may be painful), readily distinguishes a sprain from any fracture of the bones of the articulation. It is not improbable that in sprains of the knee-joint, the interior of the articulation is occasionally injured; that the crucial ligaments are stretched; and that some of their fibres give way occasionally, breaking in their centres, or detached by their extremities from the bone. We lately had an example of a severe injury of the knee-joint, in which the anterior crucial ligament must have suffered great violence. The fibres of this structure did not give way, but the portion of the tibia to which they were naturally connected was torn up with the crucial ligament. We are not aware that such an accident as this has been before noticed, although it is probable that all complete luxations of the knee-joint must be preceded by such a lesion.

A young man, aged 25, was admitted into the Richmond Hospital under the care of Dr. Hutton, on the 11th of December, 1837, with an injury of the left knee-joint, which occurred when wrestling. Being intoxicated at the time his account of the manner in which the accident occurred could not be depended upon. The joint was much swollen, very tense, and painful; no fracture, and no other deformity than that occasioned by the general swelling of the joint could be detected. The limb was maintained in the semiflexed position and on the outside. Inflammation and symptomatic fever ran very high, and the pain was excessive, especially on the least motion of the joint. On the eleventh day the pain and swelling had diminished. He could then raise the limb from the bed, but could not increase the amount of flexion. On the seventeenth day symptoms of diffuse inflammation set in; these rapidly increased, and on the twenty-fourth day from the receipt of the injury he died. The knee-joint was found to contain eight ounces of purulent matter, in which flakes of lymph floated; the synovial membrane was soft, pulpy, and vascular; the circumference of the cartilages covering the condyles of the femur was in a slight degree absorbed. On flexing the joint, the spine and central portion of the head of the tibia, with a considerable portion of its left articulating surface, were found torn up from the rest of the bone in one piece, (*fig.* 10,) and remained attached to the anterior crucial ligament.

Fig. 10.



Anterior crucial ligament torn up with portion of tibia.

Rupture of the quadriceps extensor tendon from its attachment to the superior border of the patella.—The muscles and tendons around the knee-joint are very seldom the subject of accident. We have never heard of any accidental rupture of the tendons of the hamstring muscles; we have, however, known some instances of rupture from the upper edge of the patella of the muscular and tendinous structure attached to the superior edge of this bone, consisting of the combined muscular and tendinous attachments, of the rectus, cruræus, and vasti muscles. A person who has met with this accident cannot rise from the ground, nor can he stand when raised without being sustained by two persons; when he attempts to lean his weight on the affected limb, it yields and bends forwards. On examining the knee we observe between the superior border of the patella and broken tendon a separation of one inch, which is diminished when we extend the leg, and increased much when we flex it. If we introduce our fingers into the bottom of this depression, we feel plainly the trochlea of the femur. In this case, as may be expected in all analogous accidents, there is much effusion of synovial fluid, which distends the interior of the joint; and it is probable that the synovial membrane does not escape laceration.

Patrick Dignam, æt. 69, was admitted into the Richmond Surgical Hospital on the 15th of December, 1839, for a rupture of the tendon of the rectus cruris. He stated that about a week previously, while carrying on his back a load of about two hundred weight, he slipped and fell backwards, and in making a violent muscular effort to recover himself, he felt something snap about his knee. He fell backwards, and was unable to rise without assistance. When placed on his sound limb, he found he could not elevate the affected one; he could only flex it. Whenever he attempted to put the limb under him, it quite failed him, his knee giving way and becoming instantly flexed against his will. It was found that considerable effusion had taken place into the knee-joint: the patella was raised up and seemed to float as it were on the synovial fluid and was very moveable; its entire outline could be easily ascertained; and when the leg was fully flexed, the patella was still quite moveable in the lateral directions. Above the margin of the patella a considerable depression existed into which the fingers could be sunk, and the posterior articular surface of the patella could be felt and the condyles of the femur also could be recognised through the skin. The ligamentum patellæ seemed to be of its natural length. The patient, when standing on the sound limb, could easily flex the affected one, but could not elevate it nor advance it in the least. When supported under each arm and desired to throw his weight on the injured limb, it instantly gave way under him, becoming suddenly flexed; and if the man were not supported, he would instantly fall forwards. It is now five months since he met with the accident, and being unable to earn his living he is obliged to seek a shelter in the poor-house. The upper edge of the patella can now be plainly felt, and the muscular fibres normally attached to this margin are separated from it fully one inch, this interval being increased in flexion. The surface of the trochlea and the condyles of the femur can be plainly felt. The man is obliged to use crutches in moving about. The result has been unfavourable, but it is to be recollected that the man was of a weak and debilitated frame and neglected to seek assistance for many days. A dignitary of the established church in this country, aged 70 years, who had met with this accident, was more fortunate; he was under the care of Mr. Wilmot, Professor of Surgery at the College of Surgeons, who informs me that his recovery from this accident took about a year, but that he could walk without lameness, and that the recovery was perfect.

The tendon or ligament which connects the lower extremity or front of the patella to the tibia is sometimes broken transversely. This rupture sometimes takes place across the fibres of the ligament, and sometimes one or other of the extremities of the tendon is detached from the bone to which it is naturally connected. This rupture usually takes place in a fall upon the knee, the leg being at the time carried suddenly in the greatest possible degree of flexion while the patella is drawn upwards by the contraction of the extensor muscles. We recognize this rupture by the following signs: the patient cannot raise himself from the ground; the leg has a singular tendency to flex itself, and cannot voluntarily be extended. If we examine the knee immediately after the accident and before any swelling has supervened, we observe that the patella is elevated, that its lowest point is now directed forwards, that a great degree of lateral movement can be communicated to it, and that its ligament is preternaturally relaxed. We observe underneath the skin at the place of the rupture a depression or considerable vacuum. If we push the finger from below upwards underneath the apex of the patella, we can elevate this bone so as to distinguish by the touch the eminence which separates the two articular surfaces of the tibia from each other. Such signs leave no doubt of the rupture of the ligament of the patella; but as this rupture takes place as a consequence of a fall upon the knee, and as this part is more or less contused, there follows sometimes so considerable a swelling that it is impossible to recognize the rupture. It is not until after the disappearance of the swelling that we can often assure ourselves of the true nature of the accident, Under careful management complete recovery takes place.

(Robert Adams.)

LACRYMAL ORGANS, or lacrymal passages, *organa lacrymalia* s. *viæ lacrymales;* Fr. *Les organes lacrymaux* ou *voies lacrymales;* Ital. *Gli organi spettanti alle lagrime;* Germ. *Die Thränenorgane.*

Under this head it is proposed to describe not only the lacrymal organs properly so called, but also the eyelids and conjunctiva. This article therefore comprehends all the accessory or protecting parts of the eye *(tutamina oculi* of Haller) except the orbit and muscles of the eyeball, for which see the articles FACE and ORBIT. Those parts of the orbit directly connected with the lacrymal organs are however noticed here.

I. The eyelids.—*Palpebræ.** Fr. *Les paupières;* Ital. *Le palpebre;* Germ. *Die Augenlieder.*

The eyeball is invested in front by a mucous membrane called *conjunctiva.* Towards the margin of the orbit, this membrane leaves the eyeball and forms together with the skin, with which it is continuous, two horizontal folds, an upper and a lower, intended occasionally to cover and so to protect the delicate and transparent front of the eyeball. The folds thus formed by the application against each other of a layer of mucous membrane and a layer of skin are *eyelids.*

Such is the simplest idea of eyelids, and such are they found in the salamander and axolotl among reptiles, and so far as in certain instances they exist among fishes; such even is their state in man and the higher animals at the commencement of development. But, as in the perfect condition of the organ of vision, it is essential that the eyelids should admit of being readily drawn over the front of the eyeball, and as readily retracted in order again to permit the access of light, so something more than a mere tegumentary fold was required to constitute a perfect eyelid. There was, in fact, required something to impart firmness, especially to the margins of the folds,—a structure which, whilst it served as an advantageous point on which the muscles necessary for the movements of the eyelids might exert their action, should cause no undue pressure on the eyeball, but rather give it an equable support and shield it from that irregular compression which might otherwise have been produced. All these desiderata we find supplied by a thin fibro-cartilaginous lamina, called *tarsal cartilage,* contained in either eyelid, within the fold formed by the skin and conjunctiva.

The tarsal cartilages do not occupy the whole of the folds, but only a part at their free margins. Between the upper edge of the carti-

* Palpebræ, a palpitando, quod palpitare et tremere videantur, propter citissimum et frequentissimum motum.

lage of the upper eyelid and the lower edge of that of the lower, respectively, and the corresponding edges of the orbit, there intervenes a cellulo-membraneous expansion. This (and in the upper eyelid, the expansion of the levator palpebræ superioris,) together with the conjunctiva on its inside and the skin on its outside, serves as it were the office of a loose hinge for the firm part of the eyelid. But the pivots on which the motions of the eyelids, especially of the upper, more immediately take place, are the angles of the eye. The upper eyelid, indeed, moves somewhat in the manner of the visor of a helmet, its firm part, when the eye is open, being drawn up and retracted within the margin of the orbit whilst its loose part is thrown into folds.

External conformation of the eyelids.—The extent and form of the eyelids are best seen when they are closed in sleep. The convexity of their external surface then bespeaks a corresponding concavity of the internal adapted to the prominent front of the eyeball. The opening between the two eyelids is called the palpebral fissure, *rima palpebrarum*. In the closed state of the eye, this fissure represents a mere curved line with the convexity downwards; but on account of the way in which the eyelids are moved, it is, in the open state, a wide elliptical aperture.

It is chiefly by the motions of the upper eyelid that the open or closed state of the eye is commonly produced. The upper eyelid is larger than the lower, and in the closed state of the eye from relaxation simply, as during sleep or in death, it covers much more of the front of the eyeball than the lower. But in forced closure of the eye by the action of the orbicularis palpebrarum muscle, the lower eyelid is drawn up, being impressed at the same time with a horizontal movement towards the inner angle, and meets the upper half-way, so that the latter cannot descend so far as it does during sleep. Hence, in active closure of the eye the skin of the upper eyelid is thrown into folds, whereas, in passive closure, it is smoothly extended in a convex form over the eyeball. The lower eyelid is capable of pretty extensive motion. It can of itself alone cover almost entirely the whole front of the eyeball, either when the upper eyelid is held immoveably retracted under the edge of the orbit, or in that morbid shortening or retraction of the upper eyelid known by the name of *lagophthalmos*. But as the covering of the eye by the lower eyelid is always the effect of a muscular exertion, the eye in lagophthalmos will not be covered during sleep, hence the lower can never serve as a substitute for the upper eyelid.

Sir Charles Bell* says, " Anatomists have sought for a depressor of the inferior eyelid, seeing that it is depressed, but such a muscle has no existence and is quite unnecessary. The levator palpebræ superioris opens wide the eyelids, depressing the lower eyelid at the same time it elevates the upper one. If we put the finger upon the lower eyelid so as to feel the eyeball when the eye is shut and then open the eye, we shall feel that during this action the eyeball is pushed outwards. Now the lower eyelid is so adapted as to slip off the convex surface of the ball in this action and to be depressed, whilst the upper eyelid is elevated." I believe the following to be what is usually observable in regard to the motions of the lower eyelid: the lower eyelid is drawn up over the eye by a muscular exertion; when that exertion is discontinued it falls back into its former state simply by its own elasticity and that of the integuments of the cheek. It is only in the forced state of looking downwards that the prominence of the cornea forces down the lower eyelid, in the manner described by Sir Charles Bell. It is to be remembered, however, that in the act of looking downwards, whilst the prominence of the cornea forces down the lower eyelid, the upper, contrary to what might be inferred from Sir C. Bell's statement as quoted above, is depressed, instead of being elevated.

In winking the upper eyelid falls and the lower rises considerably.

The free margins of the eyelids are broad surfaces. That of the upper eyelid is about one-twelfth of an inch broad; that of the lower about one-fifteenth. The edge bounding the margin anteriorly corresponds to the insertion of the eyelashes and is round. The posterior edge is much sharper and more defined than the preceding, and is the place where the delicate integument of the margin of the eyelid is continued into the palpebral conjunctiva.

On the margin of either eyelid between the two edges or boundaries just described, but nearer the posterior than the anterior, and parallel to them, there is observable, on close inspection, a row of minute pores—the excretory mouths of the Meibomian follicles.

The margins of the eyelids have been said to present a slope towards the eyeball, so that their outer edges only meet, when the eye is closed; and hence is produced a sort of channel between them and the eyeball of a triangular prismatic shape, which serves to lead the tears to the inner corner of the eye. Such a conformation, if it exists in the upper eyelid, is very slight and is amply compensated for by the slope in the opposite direction of the margin of the lower eyelid. The fact thus appears to be that when the eyelids are closed, their margins, as has been remarked by Magendie, meet each other surface to surface as nearly as may be.

The inner and outer corners of the eye where the eyelids join are called *canthi*. The outer canthus, generally speaking, forms an acute angle; but on close examination, it is observed that the apex is rounded off, somewhat prolonged and turned slightly downwards. The conformation of the inner canthus is altogether peculiar and rather complicated. At the inner canthus the palpebral fissure is prolonged into a sort of secondary fissure;

* The Nervous System of the Human Body, p. 186.

hence, when the eye is open, the apex of the angle formed by the inner canthus is broader and to a much greater degree prolonged than the outer; it is also rounded and turned downwards, but likewise in a much greater degree. The margins bounding the secondary fissure being destitute of cartilage are not firm and square but soft and rounded.

Where the margin of either eyelid is continued into the margins bounding the secondary fissure in question, there is observed on slightly everting the eyelids a small prominence, and in the apex of it a minute aperture, larger however than those above mentioned of the Meibomian follicles. The eminence is called *lacrymal papilla* and the aperture *lacrymal point*.

The fissure is closed by the action of the orbicularis muscle at the same time as the eyelids; but its margins, especially at the lacrymal papillæ, come completely into contact before they do. The space within the inner or nasal canthus is called *lacus lacrymalis*. The lacrymal papillæ and their points are turned in towards it, ready to take up the tears as they collect.

At the bottom of the lacus lacrymalis, there is seen a small reddish glandular body, the *lacrymal caruncle*, and between the latter and the white of the eye a *semilunar fold* of pink-coloured conjunctiva.

Eyelashes, *Cilia,** Fr. *Cils;* Ital. *Le ciglia;* Germ. *Die Augenwimpern.* Every one knows the conformation of the eyelashes. How that they are stiff compressed hairs, increasing at first in thickness from their root, then gradually tapering to their free and slender extremity; how that they spring from the anterior edge of the palpebral margins; how that those of the upper eyelid are stronger and more numerous than those of the lower; how that those in the middle are longer than those towards the corners of the eyelids; and how that those of the upper eyelid are curved upwards and those of the lower eyelid downwards, so that their convexities regard each other. In regard to the curvature it is to be remarked that it is not gradually throughout the whole hair but is betwixt the thickest part and the root. There is another slight but variable curvature towards the extremity.

The skin of the eyelids is continuous with and similar to that of the face, only somewhat more delicate. The skin of the upper eyelid is more delicate than that of the lower.

The eyebrows, *supercilia*, Fr. *Les sourcils;* Ital. *Le sopraciglia;* Germ. *Die Augenbraunen* (*fig.* 11). The external appearance of the eyebrows is too well known to require any particular description. Their prominence is produced partly by the superciliary arches of the frontal bone over which they lie, but principally by a cushion of cellular and adipose tissue underneath the skin, together with the roots of the hairs and muscular substance. The hairs of the eyebrow are, generally speaking, directed from within outwards, but internally, especially where they exist over the root of the nose, they are inclined in the opposite direction. Those immediately over the root of the nose indeed cross each other. Besides the general direction from within outwards of the majority of the hairs of the eyebrows, it is to be remarked that the uppermost ones are inclined downwards and the lowermost ones upwards, so that they are raised into a kind of ridge along the middle line of the eyebrow, an arrangement which presents a pleasing appearance of regularity. The eyebrows are capable of very free motions, and these are in close connexion with the affections of the mind; hence the eyebrows have always been considered a very important physiognomonical feature. The movements of the eyebrows are effected by muscles inserted into their skin. These muscles are: the frontalis, which elevates the eyebrows; the upper and outer fibres of the orbicularis palpebrarum, which depress them, and the corrugator supercilii, which draws them inwards. For their description, see article FACE.

The eyelids act in conjunction with the iris on many occasions; thus, in a weak light and in the act of looking at distant objects, the eyelids are widely opened at the same time that the pupil is dilated; when the eye is exposed to a strong light, on the contrary, or in looking at near objects, the palpebral fissure is contracted along with the pupil. In sleep complete closure of the eyelids is associated with very great contraction of the pupil.*

* See farther on this subject, Tourtnal, Ueber die Function der Augenlider beim Sehen. in Müller's Archiv, No. iii. 1838.

Internal structure of the eyelids.—The tarsal cartilages may be looked upon as the skeleton of the eyelids, and the membraneous expansion intervening between them and the margins of the orbits as connecting ligaments. The latter, indeed, are called the *tarsal ligaments*, although they do not in reality possess a ligamentous structure, but consist merely of dense laminar cellular membrane. On the inner surface of the tarsal cartilages and tarsal ligaments the palpebral conjunctiva adheres. On the outer surface are the palpebral and ciliary portions of the orbicularis palpebrarum muscle, over which is the skin. Moreover, incorporated with the superior tarsal ligament is the expansion of the tendon of the levator palpebræ superioris muscle. Imbedded in the substance of the tarsal cartilages lie the Meibomian follicles. Underneath the skin and the ciliary portion of the oroicularis palpebrarum muscle, the roots of the eyelashes lie close on the tarsal cartilages.

Tarsal cartilages.—Tarsi;* Fr., *Les Tarses;* Ital., *I tarsi;* Germ., *Der Augenliedknorpel.* These are thin plates of fibro-cartilage, convex on the outer surface, concave on the inner, to be adapted to the front of the eyeball. The upper is the larger. One of their margins is thick and straight, the other thin and curved, especially so in the upper, which therefore represents in some degree a segment of a circle, whilst the lower is little more than a narrow stripe. The thick and straight margin, called the *ciliary*, forms the margin of the eyelid; the thin and curved margin, called *orbital*, degenerates into the membraneous expansion already mentioned under the name of *tarsal ligaments*. Towards the outer canthus the orbital margins of the tarsal cartilages run into the ciliary ones at an acute angle, whilst towards the inner canthus they form an obtuse angle by their junction. The transverse length of the tarsal cartilages is somewhere about an inch, the breadth of the upper cartilage at its broadest part about one-third of an inch, the breadth of the lower cartilage only half as much. At the inner canthus the tarsal cartilages extend no farther than the lacrymal points, and at the outer canthus they stop close to the commissure of the two lids.

As to the intimate composition of the tarsal cartilages, they consist of what is called fibro-cartilage, a microscopically fibrous substance, without any of the corpuscles of common cartilage.

In the human lower eyelid, the thickness of this substance is inconsiderable, and its consistence not so great as in the upper. In the lower animals it is in the same state in both eyelids. This is what has led Zeiss† to say that he never found a real cartilaginous tarsus in the human lower eyelid, nor among the lower mammifera in the upper eyelid either. "In the sow only," says he, "there is a nearer approach to a tarsal cartilage than is to be found in any other of the lower animals." Müller* has very well explained away all this difference of opinion, by showing that the dense cellular tissue which, according to Zeiss, occupies the place of tarsal cartilage in the human lower eyelid, and in both those of the inferior mammifera, is the same tissue, as the more consistent fibro-cartilage of the human upper eyelid, only in a less condensed state.

The Meibomian glands are commonly described as being situate between the palpebral conjunctiva and tarsal cartilage. Winslow, Haller, and Zinn describe them as lying in *grooves* on the posterior surface of the tarsal cartilages. The Meibomian glands are seen very distinctly from the inside of the eyelids, as if they were immediately underneath the conjunctiva. But if the skin and orbicularis muscle be removed from the outside, these glands become equally visible there. "Where, then," asks Zeiss,† "do they lie,—before or behind the tarsal cartilage?" Examination of sections of the cartilage shows that the Meibomian glands *lie in the substance of the tarsal cartilage itself;* and in the human lower eyelid and in both those of the lower animals, in the less consistent fibrous structure which there composes the tarsus.

At the outer canthus the cellulo-membraneous expansions called tarsal ligaments are stronger, and form bands which decussate and thus tie the tarsal cartilages to each other and to the outer margin of the orbit. These bands compose what is called the *external palpebral ligament*.

The *internal palpebral ligament* is the tendon of the orbicularis palpebrarum muscle,—*tendo oculi*, or *tendo palpebrarum*. This, to adopt the description of Professor Harrison of Dublin, "is a small horizontal tendon, nearly one quarter of an inch in length. It is inserted internally into the upper end of the nasal process of the superior maxillary bone; thence it passes outwards and backwards to the internal commissure of the eyelids, where it forks into two slips which enclose the caruncula lacrymalis, and are then inserted each into the tarsal cartilage and the lacrymal duct."‡

Orbicularis palpebrarum muscle.—This is described in the article FACE, vol. ii. p. 221. Here we shall only advert to some particular points in its history. The fibres of the orbicularis pertaining to the upper eyelid arise from the internal angular process of the frontal bone, and from the upper edge of the tendo palpebrarum, and proceed, forming a curve, at first upwards and outwards, and then downwards and outwards, within the upper eyelid and along and over the upper edge of the orbit towards the temple and outer angle of the eye. Here they meet those of the lower eyelid which have come from the nasal process of the upper jaw-bone,

† L. c. p. 240, and op. cit. Bd. v. S. 216. See also Sichel in Lancette Francaise, Gazette des Hopitaux, No. 53, 55, and 57. Paris, 1833.

‡ Dublin Dissector, 4th ed. p. 6.

and from the lower edge of the palpebral tendon, curving at first downwards and outwards, then upwards and outwards, within the lower eyelid and along the edge of the orbit, extending some way down over the cheek. The part of the orbicularis more immediately contained within the eyelids, sometimes called the *palpebral* and *ciliary* portions, in contradistinction to the outermost fibres, which are without the eyelids, and encircle the base of the orbit, therefore called the *orbital* portion, consists of pale thin fibres, of which those at the margin of the eyelids are collected into a considerable fasciculus, having interposed between them and the tarsal cartilage the roots of the cilia. At the outer canthus the upper and lower fibres intercross and adhere to the external palpebral ligament. That many of the fibres of the orbicularis are inserted into and exert their action in a great degree on the skin of the eyelids, may be easily ascertained in the living person, by observing, during the action of closing the eye, the traction of the skin of the eyelids towards the nasal canthus. By this traction, the skin, especially in the lower eyelid, is very much corrugated. This corrugation of the skin of the lower eyelid by the action of the orbicularis is greatest right over the lower part of the lacrymal sac,—that part which we commonly press upon when we want to evacuate any accumulation of mucus or tears,—that part where abscess of the sac generally bursts and leaves a fistulous opening,—that part which we open in the operation for so-called fistula lacrymalis. This part of the lacrymal sac must therefore be immediately affected by the contraction of the muscle, and the pressure thus produced, together with that on the upper blind end of the sac by the superior fibres, will promote the transmission of the tears and conjunctival mucus into the nasal duct.

The great use of the orbicularis palpebrarum is to close the eyelids; but in effecting this it acts at a disadvantage, inasmuch as its action on the eyelids is not direct, but oblique; therefore they are brought together only by being drawn horizontally inwards, though it is the lower eyelid alone which yields to this latter movement. We may imitate in some degree the mode of action of the orbicularis, but in an opposite direction, by pressing the skin immediately outside the outer canthus, towards the temple.

Levator palpebræ superioris muscle.—This is the antagonist of the upper part of the orbicularis. It is a weak slender muscle, but then it has the advantage of exerting its action in a direct manner. It extends from the bottom of the orbit to the superior tarsal cartilage, lying immediately underneath the roof of the orbit. It is the longest of all the muscles of the orbit. Thin and triangular, it rises by its apex, which is a short tendon, from the upper edge of the optic foramen. The fleshy body of the muscle gradually increases in breadth as it proceeds forwards; then bending downwards over the eyeball, its insertion takes place by a broad thin tendinous expansion, the base of the triangle, into the upper margin and anterior surface of the superior tarsal cartilage, being incorporated at the same time with the so-called tarsal ligament. It is by the action of this muscle that the upper eyelid is drawn up and retracted within the orbit.

Having thus described the skeleton and muscles of the eyelids, it remains to consider their investments and appendages. The investment of their inner surface, the *palpebral conjunctiva*, will be described farther on, along with the rest of the conjunctiva. The skin of the eyelids lies over the fibres of the orbicularis palpebrarum. It is very fine and destitute of hairs, but contains minute sebaceous follicles. The latter are sometimes, especially in the lower eyelid, enlarged, and give out a morbid secretion, which is hard, and forms those horny excrescences occasionally met with in old persons.

Cellular tissue of the eyelids.—The conjunctiva investing the inner surface of the tarsal cartilages adheres without the intermedium of any cellular tissue. The connection between the two structures is immediate and intimate, as in the compound membranes called fibro-mucous. The rest of the palpebral conjunctiva adheres by cellular tissue. The palpebral and ciliary portions of the orbicularis muscle are connected on the one hand to the tarsal cartilages and other subjacent parts, and on the other to the superjacent skin, by a laminar cellular tissue, which, like that in some other parts of the body, is not combined with the adipose tissue. Being rather loose, the cellular tissue of the eyelids becomes readily infiltrated by effused fluids, as in *œdema* and *emphysema*. It is not unfrequently the seat of abscess.

Roots of the eyelashes. From the anterior edge of the free margins of the eyelids, the eyelashes spring. They are inserted three or four deep, especially in the middle. The capsules of the bulbs of the eyelashes lie close on the tarsal cartilage under the ciliaris muscle and skin, extending to the depth of about one-eighth of an inch. One of the operations for *trichiasis* is to extirpate the roots of the eyelashes, but it is very difficult to remove them all, the oozing of blood is generally so great. When the part has healed after the operation, and the case seems doing well, a hair or two will often be found here and there sprouting out again.

Connected with the roots of the eyelashes, as with other hairs, are small sebaceous glands, consisting of minute but distinct lobules or grains closely surrounding the capsule, into which they send one or more excretory ducts.*

Meibomian glands. Glandulæ Meibomianæ s. palpebrarum sebaceæ; — Fr. *Les glandes de Meibom;*—Ital. *Le glandule Meibomiane;* -Germ. *Die Meibomschen Drüsen.*

* Gurlt, Vergleichende Untersuchungen über die Haut des Menschen und der Haussäugethiere, besonders in Beziehung auf die Absonderungsorgane des Haut-talges und des Schweisses. In Müller's Archiv, 1835, p. 399.

† Zeiss. Fortgesetzte Untersuchungen über die Anatomie und Pathologie der Augenlider von Dr. B. Zeiss in Dresden. In Ammon's Zeitschrift, &c. B. 5, p. 216.

These are elongated more or less compound follicles, secreting a peculiar sebaceous matter intended as an ointment to protect the delicate integument of the margins of the eyelids from any irritation which might result from friction, or the frequent contact of the tears, and also to preserve to it that peculiar degree of sensibility which, like all other transition structures from skin to mucous membrane, it possesses. The Meibomian glands lie imbedded in the substance of the tarsal cartilages. They are arranged close and parallel to each other, and generally speaking in a direction at right angles to the ciliary margin of the eyelids, where they open in that row of minute apertures already mentioned. There are between thirty and forty Meibomian glands in the upper eyelid, but not so many in the lower, in which also they are shorter in consequence of the difference in breadth between the upper and lower tarsus. Sometimes two glands are united towards their orifice; sometimes, on the other hand, at their end. Frequently the tail of the gland bends laterally and describes an arch. The structure of the Meibomian glands consists essentially in a central canal running from one extremity to the other, like the duct of the pancreas, and around that canal glandular loculi or cryptæ opening into it directly, or through the medium of each other. The duct suddenly contracts before opening on the margin of the eyelid. In a transverse section of the Meibomian glands this canal is seen, according to Zeiss, as a small hole around which are placed from five to six glandular grains.

The Meibomian glands of the sow are small; representing merely a short cyst subdivided into several loculi. The glands of the eyelashes in the same animal are, on the contrary, large. The Meibomian glands of the sheep, dog, and fox, are long very thick-walled bodies, in the middle of which there is a wide canal. Ranking next in complexity of structure are the human Meibomian glands. Those of the horse, ox, goat, and cat, Zeiss found still more complex, consisting of lobes, lobules, and granules.*

The secretion of the Meibomian glands is a mild, yellowish, unctuous substance, of the consistence of lard. Occasionally the external orifice of one or more of the Meibomian ducts becomes covered by a thin film, apparently of epidermis. This prevents the escape of the secretion, which accumulating raises up the film into a small elevation, like a phlyctenula. This does not actually cause pain, but gives rise to uneasiness in the part when the eyelids are moved: the film is easily broken, and the accumulated secretion removed on the point of a pin.

Hordeolum, or stye, according to some, is abscess of the Meibomian glands; according to others, a small boil implicating the cellular tissue at the margin of the eyelid. Zeiss† suspects it has its seat in the capsule and glands of the roots of the eyelashes. Abscess of the Meibomian glands does occur, and gives rise to a tumour on the edge of the eyelid like a stye, but the nature of the case is seen on everting the eyelid. There can be no doubt that the roots of the eyelashes are involved in the disease, because the hairs at the part affected generally fall out at the end. Dr. Zeiss proposes to anticipate this result by plucking them out at once, and he says that by this procedure the progress of the complaint is arrested, a thing, certainly, occasionally very desirable. In a small inflammatory tumour at the root of a hair on the cheek, I have obtained such a result from plucking out the hair.

II. The conjunctiva, semilunar fold, and lacrymal caruncle.

The conjunctiva in general.—*Tunica conjunctiva* seu *adnata*. Fr. *La Conjonctive.* Ital. *La Congiuntiva.* Germ. *Die Bindhaut.* The conjunctiva is that membrane which lines the posterior surface of the eyelids, and covers the front of the eyeball to the extent of about a third of its whole periphery. This disposition has given rise to the distinction of a *palpebral* and *ocular* conjunctiva. Towards the margin of the orbit, all round the circumference of the eyeball, a cul-de-sac is formed by the reflection

* Zeiss's papers in Ammon's Zeitschrift, B. iv. and v., already quoted.
† Locis citatis.

and continuation with each other of these two portions of the membrane. It is by this continuity that the eyelids and eyeball are held in connexion, hence the name *conjunctiva*, and that the orbit is closed in and cut off from all communication with the space between the eyeball and eyelids.

The space between the eyelids and eyeball we shall distinguish by the name of *oculo-palpebral space of the conjunctiva*, a name, the necessity for which appears from this, that in common language, when it is said a foreign body has got *into the eye*, it is only meant that it has got into the oculo-palpebral space of the conjunctiva. The propriety of the name moreover will become more evident when the space in Serpents and Geckoes comes under consideration, for in them it is a closed cavity, (in serpents already designated by Jules Cloquet* oculo-palpebral sac of the conjunctiva,) receiving the lacrymal secretion and communicating with the exterior only by the connexion it has with the nose through the nasal duct.

What are called the *superior* and *inferior palpebral sinuses of the conjunctiva* are those parts of the oculo-palpebral space under the upper and lower eyelids respectively, where the ocular and palpebral portions of the conjunctiva are reflected and continued into each other, forming a cul-de-sac. The conjunctiva is here loosely attached to the subjacent cellular and adipose tissue, &c. of the orbit, and forms folds constantly varying with the motions of the eyeball and eyelids. The superior palpebral sinus of the conjunctiva is deeper than the lower, the reflection of the conjunctiva from the eyelids upon the eyeball being when the eyelids are passively closed: above, at the distance of about seven-tenths of an inch from the margin of the upper eyelid, and below, at about three-tenths of an inch from the margin of the lower. The cul-de-sac formed by the reflection of the conjunctiva does not lie very deep within the outer canthus, speaking in reference to it alone, though as near the edge of the orbit as above or below.

The looseness of the folds formed by the conjunctiva at the upper and lower palpebral sinuses and within the outer canthus, together with the peculiar nature of its disposition at the inner canthus, presently to be noticed, allows of the free motions of the eyeball in all directions. These folds may be readily seen on everting either eyelid, as also the continuity of the conjunctiva from the eyelid to the eyeball by requesting the person to look upwards, if it is the lower eyelid which is everted, downwards in the contrary case.

In operations on the eyeball when the eyelids are held apart unskilfully, the folds are thrust out between the eyelids by the action of the orbicularis muscle, so that they almost bury the front of the eyeball and consequently impede the operator.

By long-continued catarrhal ophthalmia and the abuse of blue stone and similar escharotics, the conjunctiva is apt to become contracted and thickened, and to acquire at the same time a callous articular surface. In such cases the contraction tells very much upon the looseness of the folds of the conjunctiva at the upper and lower palpebral sinuses, which may indeed be said to be obliterated. The consequence of this is great restriction in all the movements of the eyeball.

Foreign bodies which may have entered the oculo-palpebral space sometimes get lodged in the palpebral sinuses of the conjunctiva, especially the upper, and may be retained there for a length of time without causing much or any irritation, the conjunctiva being there so loose and the adjacent cellular and adipose tissue of the orbit so soft that the body is not much pressed upon by the opposing surfaces. The contrary is the case when the foreign body lies between the eyeball and the firm part of the eyelid, for here its irritation excites the orbicularis muscle to stronger action which serves but to aggravate the distress.

Disposition of the conjunctiva at the inner canthus.—Under this head falls to be considered the *semilunar fold*, the notice of which it will be advantageous to premise by a description of the lacrymal caruncle. In consequence of the prolongation of the palpebral fissure at the inner canthus into a secondary one, the lacrymal caruncle and semilunar fold are so exposed that their external conformation can be readily and indeed best studied in the living eye.

Lacrymal caruncle, *caruncula lacrymalis*. Fr. *La caroncule lacrymale*. Ital. *La caruncula lagrimale*. Germ. *Die Thränenkarunkel*. This is a small reddish yellow eminence having a slightly tuberculated surface, beset with very delicate scarcely visible hairs. It is situated, as has been said, within the secondary fissure of the inner canthus, and inclosed between the two slips of the tendo palpebrarum. To see the lacrymal caruncle in its whole extent, it is necessary to evert slightly the lower eyelid, when it is observed running into a point downwards and outwards. The lacrymal caruncle consists of a mass of loose fibro-cartilaginous tissue, similar to that of the tarsal cartilages, in which are imbedded follicles, secreting a fluid of the same nature as that of the Meibomian glands, and pouring it out by twelve or fifteen excretory orifices on its surface, which is invested by the conjunctiva. Anciently the lacrymal caruncle was thought to be the secreting organ of the tears, and the lacrymal points the excretory orifices.

Semilunar fold, *plica semilunaris*. Fr. *Le repli semilunaire*. Ital. *La piega semilunare*. Germ. *Die halbmondförmigen Falte*. In passing from the caruncle to the eyeball, the conjunctiva forms a vertical semilunar fold which encloses at its free edge a minute cartilage of a nature similar to the tarsal cartilages. This part of the conjunctiva is distinguished from the ocular portion by its reddish colour and greater thickness, indeed it resembles more the palpebral conjunctiva than the ocular. The concavity of the crescent, which is also the free edge of the

* Memoire sur l'existence et la disposition des voies lacrymales dans les serpens. Paris, 1821.

fold, is towards the cornea. The rolling of the eyeball outwards has a tendency to undo the fold, which on the contrary is rendered more distinct when the cornea is turned towards the nose. In quadrupeds the semilunar fold is much more developed, and contains within it a more distinct cartilaginous plate. It constitutes what in them is called *membrana nictitans*. The third eyelid in birds is the same structure carried to its highest pitch of development. In man, in whom it is very small, its component structures are readily developed to a considerable size by inflammation. According to Soemmerring the semilunar fold is larger in the negroes. We shall have occasion to recur to the membrana nictitans of quadrupeds and the third eyelid of birds.

The intimate nature of the connexion between the tarsal cartilages and the conjunctiva which lines them has been already noticed. Beyond the tarsal cartilages the adhesion of the palpebral conjunctiva becomes looser and looser until its transition into the ocular conjunctiva.

The ocular conjunctiva is smoothly spread over the front of the sclerotica, where it first passes on the latter. The interposed cellular tissue is loose enough to allow it to slide upon the sclerotica, or even to be raised up in wrinkles according to the motions of the eyeball, which are thus facilitated. But as the conjunctiva approaches the cornea it is more and more closely applied to the sclerotica and consequently less readily falls into wrinkles. The debated question of a conjunctival covering of the cornea will be considered when speaking of the intimate structure of the conjunctiva.

The cellular tissue between the conjunctiva and sclerotica is sometimes the seat of extravasations of blood, *subconjunctival ecchymosis*, sometimes the seat of an accumulation of serous fluid, as in the œdema attending erysipelatous ophthalmia. It is sometimes the seat of a more serious form of œdema, that known by the name of chemosis, and common in the purulent inflammation of the conjunctiva. It may also be the seat of emphysema, and is occasionally so of phlegmon.

Nature of the conjunctiva.—The conjunctiva forms part of that membraneous system, continuous with the skin at all the natural apertures of the body, which lines the interior of the respiratory and digestive canals, and to which, as to that lining the genito-urinary passages, the generic name of *mucous membrane* is given. Of course different parts of this system present specific peculiarities in structure and function, and this is the case even in regard to the palpebral and ocular parts of the conjunctiva, though so near each other. Some of the Germans have unnecessarily involved this subject. Thus Walther viewed the conjunctiva as *mucous* in the eyelids, *tegumentary* over the sclerotica, and *serous* over the cornea. Whence we sometimes meet in their ophthalmological works such expressions as "the conjunctiva considered as a mucous membrane," and "the conjunctiva considered as a serous membrane." In reference to these opinions of his countrymen, Müller* has thought it necessary to remark that the conjunctiva is as certainly a mucous membrane as any other of which the character has not been doubted. * * * On the other hand it has nothing in common with the serous membranes either in secretion, for the limpid secretion of the eyes is derived from the lacrymal gland, or in its form, which is not that of a shut sac.

Within the upper eyelid towards the outer canthus (*fig.* 12 *f*), the conjunctiva presents the minute mouths, nine or twelve in number, of the ducts of the lacrymal gland. At the inner canthus the conjunctiva is continuous through the lacrymal points with the membrane lining the canalicules, and so through them, the lacrymal sac and nasal duct, with the mucous membrane of the nose. At the margin of the eyelids its continuity with the skin is seen.

The oculo-palpebral space of the conjunctiva receives the tears much in the same way that the mouth receives the salivary secretions. Like other mucous membranes the conjunctiva secretes a mucous fluid which lubricates its surface and serves to protect it from the irritating action of external agents, and even from that of the lacrymal secretion which is naturally poured out on it.

Intimate structure of the conjunctiva.

Palpebral conjunctiva, *conjunctiva palpebrarum.*—The conjunctiva lining the eyelids is thicker and more vascular than that which invests the sclerotica. On the posterior surface of the eyelids, about one-twelfth of an inch from and parallel with the posterior acute edge of the margin, there is a very slight groove. Between this and the edge of the eyelid the conjunctiva is sufficiently distinct by its moist shining surface and its vascularity, from the more integument-like though delicate investment of the margin of the eyelids with which it is continuous. But it is immediately in the groove and especially beyond it that the conjunctiva, as pointed out by Eble,† first shows itself truly as a mucous membrane, that is, presents all the characters commonly ascribed to mucous membranes.

The palpebral conjunctiva consists of a *chorion*, the free surface of which presents papillæ, constituting what is called the *papillary body*, and the whole is covered by an *epithelium*.

The *chorion* of the palpebral conjunctiva is intimately incorporated with the tarsal fibro-cartilages, so that the latter and their investing conjunctiva might be considered together as constituting a compound or fibro-mucous structure. Beyond the cartilages the chorion appears in its independent and separable form as a felt-work composed of an interlacement of filamentous cellular tissue, and is the nidus for the ramification of the vessels and nerves.

Papillary body.—If the upper eyelid be

* Handbuch der Physiologie des Menschen, Bd. i, S. 429, Coblenz, 1838, or Translation by Baly, p. 436.

† Ueber den Bau und die Krankheiten der Bindehaut des Anges, p. 9. Wien, 1828.

everted and examined, the moisture being first wiped off from its surface, under different directions of the light, an appearance is observed as of a shining surface beset with small brilliant grains, as if minutely shagreened. This appearance is more or less distinct in different individuals and most so after death.

The appearance described is produced by numerous papillæ, considered nervous by Ruysch,* and small glands by Müller,† and, after him, by most other authors. Eble‡ objects to this view of the matter, and asserts that the papillæ are quite distinct from mucous glands, and are the same as the papillæ found on other mucous surfaces, and that they particularly resemble the papillæ of the mucous membrane of the gums and inner surface of the alæ nasi. Eble, however, adds that these papillæ present themselves in all the mucous membranes in a manner quite analogous to glands, and he thinks that the mucus of mucous membranes is the product of the secretion of the papillary body. And this is equally applicable to the secretion of the palpebral conjunctiva, whence it would appear that Müller and Eble really do not differ in opinion, but only in the terms they employ to express it.

The part where the papillary body appears least distinctly is between the edge of the eyelid and the groove on the posterior surface above mentioned. The palpebral conjunctiva all beyond the groove presents the papillary body in a more decided form, and the development of it goes on increasing to some distance beyond the orbital margin of the tarsus. The conjunctiva covering the lacrymal caruncle, as also the greatest part of the semilunar fold, present no papillary body. Towards the lacrymal points there is found a great number of pretty apparent papillæ.

The papillary body is very vascular. It is the morbid development of it which constitutes the so-called granulations of the eyelids in the puro-mucous ophthalmiæ; of which indeed the papillary body appears to be the peculiar seat. An inflammation suddenly affecting a healthy conjunctiva from atmospherical causes is what is conventionally called a *catarrhal ophthalmia*. If this be allowed to fall into a chronic state, or if the conjunctiva has been affected by a less marked inflammatory action for a time, the papillary body becomes hypertrophied. In this state it forms as it were a new organ ready to be affected by a form of disease which a healthy conjunctiva is not all at once so prone to assume. Mere congestion caused by over-exertion of the eyes, or by heavy caps and high tight collars, as Dr. Vleminckx thinks, together with fatigue, exposure, want of cleanliness, abuse of stimulating liquors, &c., may give rise to this unnatural development of the papillary body of the conjunctiva, and so predispose in a particular manner, on the occurrence of any atmospherical influence, to an attack of conjunctivitis, and that rather of the form of the Egyptian ophthalmia than of a simple catarrhal.

Epithelium of the palpebral conjunctiva.— "It is extremely difficult," says Eble,* "to distinguish this on so fine a membrane. Although I have succeeded, by maceration in boiling water, in detaching it in part from the eyelids of an ox, I have not again been able to convince myself of the exactness of the observation as I could have wished." J. F. Meckel doubted the existence of an epithelium. Eble says again that he would, however, admit its presence on the conjunctiva rather from analogy than from observation. Here is a good example of the assistance derivable from the microscope, two such observers as Meckel and Eble unable with the naked eye to determine the existence of a structure which later observers with the microscope have fully established. We shall return to the subject in speaking of the epithelium of the conjunctiva bulbi.

Sclerotic conjunctiva, conjunctiva scleroticæ. As far as vascularity goes, there is a decided difference between this and the preceding. The sclerotic conjunctiva is composed of a chorion or vascular basis of the membrane covered by epithelium. Valentin† describes between the chorion and epithelium another structure which he calls papillary.

The chorion of the sclerotic conjunctiva consists of irregularly stratified fibres of cellular tissue interwoven with bloodvessels and nerves.

"Do the conjunctiva scleroticæ and the conjunctival pellicle of the cornea also preserve a papillary body or not?" asks Eble,‡ in reference to Valentin's assertion of one. Eble admits the structure described by Valentin under the name of papillary body between the chorion and epithelium of the conjunctiva bulbi, but thinks, and correctly, that it is a very different thing from the papillary body of the palpebral conjunctiva as described by himself. Valentin's papillary body of the conjunctiva bulbi is a matter of the microscope— Eble's papillary body of the palpebral conjunctiva, though minute, is still in some degree cognisable to the naked eye. Hypertrophy of the papillary body of the palpebral conjunctiva constitutes, as has been said, what is called granular conjunctiva. We never see such a granular state of the sclerotic conjunctiva.

The following is Valentin's description of what he calls the papillary body of the conjunctiva bulbi:—It is best seen in the human eye, "when, after several days' maceration, the loosened and swollen epithelium is carefully

removed and the papillary body then separated by a shaving cut through the surface of the conjunctiva. The papillæ are seen under a microscope magnifying three hundred diameters, as yellowish red corpuscles standing close together, of an arched conical shape and presenting a round nucleus in their interior. Many of the papillæ have short pedicles. Many present at their extremity a small point or filamentous prolongation which runs towards the epithelium. Henle* thinks Valentin's papillæ are nothing but the corpuscles of the epithelium, presently to be noticed, distorted by the action of the compressorium. It appears to me that Valentin's papillary body constitutes a structure of the same nature as the corpus Malpighianum of the skin. We know that such exists in the sclerotic conjunctiva from the circumstance that in negroes and many of the lower animals it is tinged of a black or brown colour, whilst in Isabella horses and in Swiss races among oxen it appears yellowish.

Epithelium of the conjunctiva. The discovery of a characteristic structure in epithelium enables us to determine its existence even when so delicate as not be separable as a distinct layer. It may appear merely as a tenacious mucus little more than perceptible to the naked eye, but examined under the microscope it is found to consist of minute polygonal cells, flat and containing a central nucleus. These corpuscles aggregated together more or less closely and in greater or less quantity constitute the substance of epithelium. The epidermis is essentially of the same structure; as also the corpus Malpighianum, only when this is coloured, the cellules are found to contain colouring particles, as is remarkably the case in the black pigment of the eye, the small hexagonal bodies composing the membrane of which belong to the same category as the corpuscles of the epithelium or corpus Malpighianum.

According to Valentin the epithelium of the conjunctiva consists of rhomboidal or quadrate cells lying close together, the boundaries of which are formed by simple lines. In every cell there is found without exception a somewhat darker and more compact nucleus of a round or largish form. The average diameter of these cells, in the human eye, is about the two-thousandth of an inch. The nuclei are about half the size.

Thickening of the epithelium takes place in ectropium and callous granulations. What is called cuticular conjunctiva is at the same time a general contraction of the whole conjunctiva with a thickened and dry state of the epithelium.

Does the conjunctiva extend over the cornea? Every one admits the existence of a layer on the anterior surface of the cornea, quite different from its proper substance, and apparently a continuation of the conjunctiva covering the sclerotica, but this layer on the anterior surface of the cornea does not present exactly the same, or at least all, the anatomical and chemical characters as the sclerotic conjunctiva. What of it can be raised is like epidermis or epithelium, coagulated and rendered white by the heat applied to separate it, and moreover it is not vascular, the vessels seen ramifying on the surface of the cornea in some inflammations being situated underneath it.

What is the nature of the superficial layer of the cornea? It is composed of two lamellæ. The more superficial constitutes a very fine but firm epithelium. According to Valentin, after sixteen or twenty-four hours' maceration, the epithelium separates from the cornea. The cells have in this case lost a little in transparency and are somewhat distended. The nuclei appear more or less swollen by the action of the water. The other lamella situated underneath the epithelium is more loose in its cohesion, and is what Valentin considers the same structure as the papillary layer described by him in the ocular conjunctiva. Valentin says that a chorion or fibrous layer does not exist in the conjunctival extension over the cornea. The bloodvessels derived from the sclerotic conjunctiva run merely betwixt the papillary body and the surface of the proper substance of the cornea. They are very delicate and extremely difficult to inject.

Römer* has described the arteries of the conjunctiva corneæ from injections. The fine twigs of the arteries of the sclerotic conjunctiva unite together around the margin of the cornea into a vascular wreath or circle. From this there arise very numerous branches which run from the circumference towards the centre of the cornea, and in their course make two or three very fine subdivisions. Their ends bend distinctly inwards, and appear to penetrate the proper substance of the cornea.

Having thus shown on the surface of the cornea the existence of an epithelium and a structure, called by Valentin a papillary body, similar to what is found on the surface of the sclerotic conjunctiva, as also a stratum of bloodvessels, we must admit a cellular support for those vessels, however delicate. If so, the bloodvessels and cellular tissue would constitute the essential elements of a chorion.† We can only explain the development of those extensions of membrane like sclerotic conjunctiva, over the cornea by supposing an irregular and undue development or hypertrophy of these elements.

The question, "Does the conjunctiva extend over the cornea?" may be considered as answered in the affirmative by the above anatomical demonstration. Morbid anatomy now comes in advantageously with its corroborative evidence. "Nothing is more in favour," says Eble, "of the existence of a con-

* Symbolæ ad Anatomiam Villorum intestinalium, imprimis eorum epithelii et vasorum lacteorum, p. 8. 4to. Berolini, 1837.

* In Ammon's Zeitschrift Bd. v. p. 21, Table 1, Fig. 9 and 11. See also Müller's Archiv, 1836; Jahresbericht, p. 28; and Henle De Membrana Pupillari, &c. Bonnæ, 1832.

† Medico-Chirurgical Transactions, vol. xxi. p. 414, London, 1838; London Medical Gazette, vol. xxiii. pp. 571, 702, 815.

junctival layer on the cornea than the microscopical structure of this membrane, for there is the greatest resemblance between the structure of the sclerotic conjunctiva and the investment of the cornea."* Eble thus retracts the opinion he formerly expressed against the existence of a conjunctival layer of the cornea.

Externally the sclerotica overlaps or encroaches on, more or less, the edge of the cornea. In certain constitutions, and especially in old persons,† I have observed that the overlapping part of the sclerotica is thicker and more opaque than usual—perhaps also encroaching more extensively on the cornea. The conjunctiva covering the overlapping sclerotica, especially when the latter is to any considerable extent, appears in its independent form with its chorion fully developed, and although it adheres to the subjacent overlapping part of the sclerotica very closely by cellular tissue, it by no means presents the same intimate union with the subjacent structure and the same rudimentary state which the conjunctival extension over the transparent cornea has. In an eye before me in which the overlapping sclerotica is to some considerable extent at the upper edge of the cornea, I easily raised up in a fold and then separated by dissection the perfectly developed conjunctiva from over the part. The conjunctiva covering the overlapping part of the sclerotica has a vascular connexion with the latter no otherwise than by the anastomoses of the proper vessels of each—a vascular connexion, which indeed subsists between the sclerotica and conjunctiva elsewhere. The disposition just described is connected with a point in the pathology of the eye, viz. the bluish white ring which is observed to encircle the cornea more or less completely in certain internal inflammations of the eye, and so frequently in what is called arthritic iritis that it has been considered a diagnostic of it, but certainly without just grounds.

Before explaining the cause of the appearance, I would request it to be remembered that the insertion of the ciliary ligament is at some little distance from the apparent margin of the cornea; that the vessels which form the red zone of the sclerotica in the internal inflammations of the eye, and in inflammation of the proper substance of the cornea, are vessels which send branches inwards to the iris, opposite the ciliary ligament, branches outwards to anastomose with those of the conjunctiva, and lastly, branches which, following the original direction, go to be distributed to the proper substance of the cornea. These vessels are not apparent in the healthy state, and one set of them only may become apparent in inflammation. Thus in inflammation of the iris, they will be apparent only as far as opposite the insertion of the ciliary ligament. Between this and the clear part of the cornea is the opaque overlapping part of the sclerotica, which of course not being in the way of the progress of the vessels towards the inflamed part, remains white as usual, and the cornea not being affected the minute branches to its proper substance remain unenlarged and unseen. Hence the overlapping part of the sclerotica is seen in contrast between the abruptly terminating red sclerotic zone on the one hand, and the transparent cornea (appearing dark on account of the dark structure behind it) on the other, forming the bluish white ring.

From this explanation the bluish white ring round the cornea ought to exist more or less in all internal inflammations of the eye, unless obscured by vascularity of the conjunctiva in inflammation of the cornea. So it does; but in persons of otherwise sound constitution and not of advanced age, the overlapping sclerotica is so transparent and sometimes also to so small an extent, that it is not strongly contrasted by the transparent cornea. It is otherwise the case, however, in certain persons, especially such as are advanced in life, in whom the encroachment of the sclerotica and fully developed conjunctiva on the cornea exists to a great degree and in a very opaque state, that the bluish white ring appears in the exaggerated distinctness which has commonly attracted the notice of surgeons.

The condition of the eye necessary for the *distinct* appearance of the bluish-white ring round the cornea occurring principally in old persons of bad constitution, and these being the very persons in whom an internal inflammation of the eye very often presents what is called the arthritic character, are circumstances which readily explain the error of supposing the bluish white ring round the cornea diagnostical of arthritic iritis.*

III.—Lacrymal organs properly so called.

Under this head are comprehended: 1. The secreting lacrymal organs, or the lacrymal gland and its excretory ducts. 2. The derivative lacrymal organs, or the passages by which the secretions of the lacrymal gland and of the conjunctival surface are drawn off into the nose, viz. the lacrymal points, the lacrymal canalicules, the lacrymal sac, and nasal duct.

The lacrymal gland and its ducts may be considered as a branched diverticulum of the conjunctiva; the derivative lacrymal organs, to use the expression of M. De Blainville, as nothing but the continuation of the conjunctiva and its anastomoses with the olfactive membrane.

1. Secreting lacrymal organs.

Lacrymal gland,—*Glandula lacrymalis;* Fr. *La glande lacrymale;* Ital. *La glandula lagrimale;* Germ. *Die Thränendrüse.*

When the lacrymal caruncle was supposed to filtrate the *succus lacrymalis,* and the lacrymal points to excrete it, the lacrymal gland was called *glandula innominata.*

The lacrymal gland (*Fig.* 13) consists of two masses, an upper and a lower. The upper mass, or *glandula lacrymalis superior,* lies in the lacrymal fossa, a depres-

* Medicinische Jahrbücher des k. k. oesterreichischen Staates; Neueste Folge. Band xvi.

† The *arcus senilis,* it is to be remembered, is not here the question.

* London Medical Gazette, vol. xxiii. p. 817.

sion of a size sufficient to receive the point of the thumb, situated in the roof of the orbit at its upper and outer angle, just within the overhanging outer extremity of the superciliary arch. The superior lacrymal gland is of an oval or triangular shape about three-fourths of an inch in its longest diameter and about half an inch across. It is flattened from above downwards. Its upper surface is convex; its lower plane or concave. The thickest edge of the gland is turned outwards. The gland is of a reddish colour and is enveloped in a thin but dense cellular coat. The lower mass of the lacrymal gland, or *glandula lacrymalis inferior*, is a loosely connected aggregation of lobules of the same glandular substance as the above. It was first described by the second Monro, who called the lobules, for distinction's sake, *glandulæ congregatæ*.*

The lower mass of the lacrymal gland is smaller than the upper, with which it is in contact above, whilst below it extends to the outer part of the upper margin of the tarsal cartilage of the upper eyelid. It lies indeed in the substance of the upper eyelid at the outer part. It is seen shining through the conjunctiva in everting the upper eyelid.

Fig. 13.

Lacrymal gland, left side.

a a, Superior mass; *b b*, inferior mass; *c*, part of inferior mass lying towards the outer canthus.

Intimate structure of the lacrymal gland.—The lacrymal gland is what is commonly called conglomerate. It belongs to Müller's compound glands with canals of the ramified type. "In the arrangement of the secreting canals of the lacrymal glands," says Müller,† "two principal forms are observed: the one is that which I discovered in the chelonian reptiles; the other, that which prevails in birds and Mammalia. In the chelonia, the gland is formed of a number of club-shaped lobes, united together by means of the different ducts which run in their interior. The duct of each lobe is pretty uniform in diameter, and into it open an innumerable quantity of microscopical tufts of cœca, which are arranged around it at right angles like the foliage of a moss on its stem." In birds, in which the lacrymal gland is very small and situate at the posterior angle of the eye, and Mammalia, the secreting canals of the lacrymal gland are regularly branched and terminate in each acinus in a number of small cells. In birds these cells are very large; and in them, and likewise in the horse, the cells can be filled with mercury from the efferent duct.

Efferent or excretory ducts of the lacrymal glands.—The lacrymal glands pour out their secretion by nine or twelve very slender excretory ducts which proceed from above downwards and open on the surface of the conjunctiva on the inside of the upper eyelid. The orifices of the ducts are placed at about one-twentieth of an inch apart from each other in a row extending about half an inch from the outer canthus inwards, parallel to but a little above the outer part of the upper margin of the tarsal cartilage, that is, at the inferior boundary of the lower mass of the gland.

The excretory ducts of the lacrymal gland were first discovered on the 11th of November, 1665, by Nicolaus Steno,* in the eyelid of a sheep. He delineated them from the eye of the calf. Moreover it appears that Steno describes vasa lacrymalia discovered in man, which opened in the membrane of the upper eyelid.†

Admitted by some and doubted by others from the time of Steno, the ducts of the lacrymal gland became a subject of dispute between Dr. William Hunter‡ and the second Monro,§ the one claiming to have observed them in the human eye before the other.

The best way to demonstrate the ducts is to stretch the upper eyelid, turned inside out, upon the finger; then wipe clean the surface of the conjunctiva, and having by close inspection at the place where the ducts open, as above described, discovered the orifices, take a short piece of human hair in the point of a forceps, and entering it at the orifice, push it on in the direction of the duct. From the orifices on the surface of the conjunctiva the ducts run nearly parallel with each other upwards.

Of two eyes before me I have in this way inserted hairs into nine orifices of ducts in the one and into twelve orifices of the other, a work which did not occupy five minutes for each eye. In both eyes there is one orifice of a duct exactly within the external commissure,

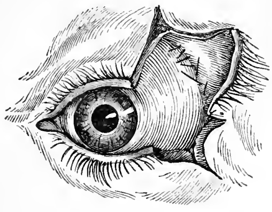
and another rather within the lower eyelid. See *figs*. 12 & 14.

Fig. 14.



A left eye with the eyelids cut in the middle, and the outer halves everted to show the orifices of the ducts of the lacrymal gland, into which hairs are inserted.

The preceding description of the lacrymal gland and its ducts shows that the latter and the lower mass at least of the former may be readily wounded along with the upper eyelid, and that in Crampton's operation for entropium, the lower mass of the gland, together with some of the lacrymal ducts, must necessarily be wounded, if the eyelid be cut through near the outer angle and to any height. In cases in which I have performed the operation, however, I have not observed any lacrymal fistula or other bad consequence follow.

Tears.—*Lacrymæ*, Fr. *Les larmes;* Ital. *Le lagrime;* Germ. *Die Thränen*. The lacrymal secretion like the salivary appears constantly to flow, though in no greater quantity than is sufficient to moisten the surfaces of the conjunctiva. The derivative lacrymal organs are in this case equal to the removal of it; but when the tears are poured out in unusual quantity, as they are, like the salivary or urinary secretion as well as that of the skin, in certain affections of the mind, they run over the margin of the lower eyelids and drop down the cheeks.

According to Fourcroy and Vauquelin there remains after evaporating the tears, about one per cent. solid substance, which consists chiefly of common salt and a yellow extractive matter perfectly soluble in water. Before drying, this appears quite similar to mucus.

2. Derivative lacrymal organs.

Previously to describing the passages by which the tears are drawn off into the nose, it will be advantageous to take a glance at the osseous groove and canal in which the principal part of those passages is lodged.

Osseous groove for the lodgement of the lacrymal sac. The lacrymal groove, *sulcus lacrymalis*, is situated at the fore part of the inner wall of the orbit. It is directed from above downwards, extending from the junction of the frontal bone with the nasal process of the superior maxillary and with the lacrymal bone, on the one hand, and to the inner and lower angle of the margin of the orbit on the other. Here it runs into the osseous canal for the nasal duct. The lacrymal groove is pretty deeply scooped out, and is about eight-tenths of an inch long and five-twentieths broad.

The outer aspect of the nasal process of the superior maxillary bone is divided by an ascending ridge, the continuation of that forming the lower margin of the orbit, into two surfaces. The posterior surface, which is the narrower, forms the anterior half of the lacrymal groove. The posterior half of the groove is formed by that narrow grooved part of the orbital surface of the lacrymal bone in front of its vertical crest. The line of junction (*shindylesis*) between the posterior margin of the nasal process of the superior maxillary bone and the anterior margin of the lacrymal runs down longitudinally in the bottom of the groove.

The *anterior margin* of the lacrymal groove formed by the ascending ridge subdividing the outer surface of the nasal process of the superior maxillary bone, is thick and rounded. The *posterior margin*, formed by the crest which subdivides vertically the orbital surface of the lacrymal bone, is thin and sharp.

Inferiorly the crest of the lacrymal bone forms a small curved prolongation directed forwards and outwards, which serves to form the commencement of the posterior wall of the osseous canal for the nasal duct. The process, which is called *hamulus ossis lacrymalis*, articulates with the orbital plate of the superior maxillary.*

The osseous canal for the nasal duct.—The osseous nasal canal, about half an inch in length, extends from the lower extremity of the lacrymal groove to the lowest meatus of the nose, at the anterior part of which it opens. Its orifice is overhung by the anterior extremity of the lowest spongy bone. The osseous nasal canal is directed a little obliquely from before backwards, and from within outwards. It is somewhat narrower in the middle than at either extremity. It is compressed from within outwards, hence a horizontal section is rather elliptical than circular.

The *anterior and outer walls* of the osseous canal are formed by a groove inclined downwards and backwards on the inner surface of the body of the superior maxillary bone, the continuation of that on the nasal process which contributes to form the lacrymal groove. The *posterior wall* of the canal is in great part formed above by the hamular process of the lacrymal bone, where it articulates with the orbital plate of the superior maxillary. The lowest part of the posterior wall is formed by the meeting together of the lacrymal process

* In man the lacrymal bone does not always form a single piece. "In a great number of cases," says M. Rousseau, "the lacrymal bone is found divided into two unequal parts, even in aged subjects. The larger contributes to form the inner wall of the orbit, the smaller is situated below and outside the preceding on the floor of the orbit; its exposed surface does not measure more than two millimetres in extent, but it dips under the vertical crest of the first portion, and contributes to form the lacrymal canal." See "Description d'un nouvel os de la face chez l'homme," in Annales des Sciences Naturelles. Paris, 1829.

of the lowest spongy bone and the posterior margin of the groove in the superior maxillary, constituting the anterior and outer walls. The *internal wall* of the osseous nasal canal is formed superiorly by a continuation of the osseous surfaces composing the lacrymal groove. Below, it is formed, in front, by a farther continuation of one of these surfaces, viz. that of the superior maxillary bone, and behind by a thin plate of the lowest spongy bone, *the nasal or lacrymal process of the lowest spongy bone*, which rises to join the inferior edge of the lacrymal. The anterior edge of this process of the spongy bone joins the posterior edge of the lower part of the lacrymal surface of the nasal process of the superior maxillary. The line of junction is thus the continuation of that at the bottom of the lacrymal groove.

Lacrymal papillæ, points and canalicules.—(*Fig.* 15.) At the inner extremity of the ciliary

Fig. 15.

a, b, c, d, superior and inferior lacrymal canaliculi; *a, a,* lacrymal points; *b, b,* the small blind dilatations presented by the lacrymal canalicules, where they bend inwards to the lacrymal sac; *c, c,* continuation of the lacrymal canalicules; *d, d,* their entrance into the lacrymal sac; *e, f, g,* lacrymal sac; *e,* blind end of the lacrymal sac; *f,* middle part of the lacrymal sac; *g,* its termination; *h, i,* nasal duct; *i,* opening of the nasal duct into the nose.

margin of each eyelid, where the fissure of the nasal canthus begins, there has been already described a small papillary eminence, *lacrymal papilla*, papilla lacrymalis, in the summit of which is a small orifice, *lacrymal point*, of such a size as to admit a thick bristle. The lacrymal points, *puncta lacrymalia;* Fr. *Les points lacrymaux;* Ital. *I punti lagrimali;* Germ. *Die Thränenpunkten;* are from their size and situation sufficiently conspicuous as not to be confounded with one of the orifices of the Meibomian follicles. In the natural state the lacrymal papillæ are inclined towards the lacus lacrymalis. The lower papilla is somewhat more prominent than the upper, and situate somewhat more towards the temple. The *lacrymal canalicules, canaliculi lacrymales, s. cornua limacum;* Fr. *Les conduits lacrymaux;* Ital. *I condotti lagrimali;* Germ. *Die Thränenkanälchen;* lead from the lacrymal points into the lacrymal sac. From the superior lacrymal point the superior canalicule proceeds upwards and outwards within the papilla a little way, then suddenly bending at an acute angle and forming at the same time a small dilatation, it runs downwards and inwards, inclosed in the fold of skin and conjunctiva forming the upper border of the fissure of the nasal canthus, to the lacrymal sac. The course of the inferior canalicule is the counterpart of the above. From the lower point it runs a short way perpendicularly downwards and outwards within the corresponding papilla, then bending abruptly and like the upper forming a small dilatation, it proceeds upwards and inwards, inclosed in the fold of skin and conjunctiva forming the lower border of the fissure of the nasal canthus, to the lacrymal sac.

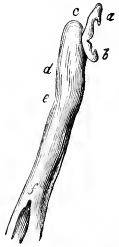
The canalicules having met each other at the commissure of the fissure of the nasal canthus, pass under the tendon of the orbicularis muscle, and open by separate orifices, close to each other however, into the anterior and outer part of the lacrymal sac. These orifices indeed are separated merely by a duplicature of the mucous membrane composing their walls.

The lacrymal canalicules have pretty firm walls of mucous membrane, which do not collapse, but when cut across are seen gaping open. The calibre of the canaliculi is about the thirtieth of an inch in diameter; that of the points is less, but these are capable of being dilated.

The canaliculi are immediately surrounded by the fibres of the internal palpebral ligament, and those of the tensor tarsi muscle.

Lacrymal sac; *saccus lacrymalis;* Fr., *Le sac lacrymal;* Ital. *Il sacco lagrimale;* Germ., *Der Thränensack.*—(*Fig.* 16). This is a membraneous reservoir of a vertically elongated form, and externally compressed, nine-twentieths of an inch long, and two-tenths broad externally.

Fig. 16.



Derivative lacrymal passages of the left side, seen from the side of the nasal cavity.

Here it is seen that the nasal duct is much broader viewed from the side than from before. *a, b,* superior and inferior lacrymal canaliculi; *c, d,* lacrymal sac; *e, f,* nasal duct; *f,* nasal orifice of the nasal duct, seen quite in its natural state.

It lies, by its inner and posterior surface, in the lacrymal groove, with the periosteum of which it is closely incorporated. Its anterior and outer surface, which lies without the groove, is immediately covered by a strong aponeurosis derived from the upper and lower edge of the horizontal tendon of the orbicularis muscle, which passes across the lacrymal sac a little above the centre. This aponeurosis adheres to the margins of the bony groove in which the sac is lodged, and there becomes continuous with the periosteum. More superficially, the anterior and outer surface is covered by the muscular fibres of the orbicularis and by the skin.

Above the lacrymal sac forms a cul-de-sac or blind end,—*finis cæcus sacci lacrymalis.* Below it passes into the nasal duct. This transition is marked by a slight contraction, sometimes inside, by a circular fold of the mucous membrane, of which both are formed.

At its anterior and outer part, a little below its upper blind end, and immediately behind the internal palpebral ligament, the lacrymal sac receives the canalicules. Overhanging the orifices of these there is a small semilunar fold of the mucous membrane of the sac.*

The nasal duct; *ductus nasalis;* Fr., *Le canal nasal;* Ital., *Il condotto nasale;* Germ., *Der Nasenkanal,* is a laterally compressed canal, about three-quarters of an inch in length, and readily admitting the passage of a probe the fifteenth of an inch thick, continued from the lower part of the lacrymal sac. It runs downwards, backwards, and a little outwards in the osseous canal already described, of which it is indeed nothing but the membraneous lining. The nasal duct is more contracted in its middle than at either extremity. It opens in the anterior and upper part of the lower meatus, at the lateral wall of the nasal cavity, and about one inch from the entrance of the nostril. Its orifice, which is overhung by the lower spongy bone, is a long fissure, oblique from above downwards and from within outwards. The obliquity of the orifice of the nasal duct is owing to the circumstance that the posterior or external wall of the membraneous part of the nasal duct descends farther than the osseous canal, and forms, by means of the folded pituitary membrane, a semi-canal, which descends in the external wall of the lower meatus, whilst the internal wall of the membraneous part of the nasal duct is shorter, and terminates where the osseous canal stops.

The lacrymal sac and nasal duct are composed of a thick soft mucous membrane, which must be considered as productive of that of the nose. Externally, this mucous membrane is united with the periosteum of the osseous surfaces in connection with the lacrymal sac and nasal duct, and as far as concerns that part of the lacrymal sac not in the osseous groove, by the aponeurosis derived from the tendo palpebrarum.

Internally, the mucous membrane of the lacrymal sac and nasal duct forms various small plicæ or rugæ. Red and villous, it is quite different from the white and smooth mucous membrane of the canalicules. Like the pituitary membrane of the nose, it secretes, in the healthy state, a clear, mild, fluid mucus.

Lacrymal or *tensor tarsi muscle.*—Here is perhaps the proper place to notice a muscle which was discovered many years ago by M. Duverney,* delineated and described by Rosenmüller† in 1805, and more recently re-described by Dr. Horner,‡ an American anatomist, with whose name it is now commonly associated.

To get a view of this muscle, Professor Horner directs us to cut through the eyelids and separate them from the ball, except at the inner canthus; then turn the lids over the nose, remove the semilunar fold and the conjunctiva in the neighbourhood, with the fatty matter, when the muscle, such as it is represented in the following description, will be seen.

"The tensor tarsi arises from the posterior superior part of the os unguis, just in advance of the vertical suture between the os planum and the os unguis. Having advanced three lines, it bifurcates; one bifurcation is inserted along the upper lacrymal canalicule, and terminates at its punctum, or near it; and the lower bifurcation has the same relation to the lower lacrymal canalicule. The base of the lacrymal caruncle is placed in the angle of the bifurcation. The superior and the inferior margins of the muscle touch the corresponding fibres of the orbicularis palpebrarum, where the latter is connected with the margin of the internal canthus of the eye, but may be readily distinguished by their horizontal course. The nasal face of this muscle adheres very closely to that portion of the sac which it covers, and also to the lacrymal canalicules. The lacrymal sac rises about a line above its superior margin, and extends in the orbit four lines below its inferior margin. The orbital face of the muscle is covered by a lamina of cellular membrane, and between this lamina and the ball of the eye are placed the semilunar fold of the conjunctiva, and a considerable quantity of adipose matter. As the bifurcated extremities of the muscle follow the course of the canalicules, they are covered by the conjunctiva. The muscle is an oblong body, half an inch in length, and about one quarter wide, bifurcated at one end; and it arises much deeper from the orbit than any acknowledged origin of the orbicularis. The su-

* Rosenmüller, op. cit. § 125.

* Œuvres Anatomiques de M. Duverney, tom. ii. 4to., Paris, 1761. After speaking of the fibres of the orbicularis which lie over the lacrymal sac, it is said (tom. i. p. 130), "Entre ces fibres, il y a un petit muscle au dédans du grand angle qui prend son origine de la partie anterieure de l'os planum et s'insere à la partie interne du tendon mitoyen ou commun à l'apposé de l'orbiculaire; c'est un petit muscle que j'ai observé il y a long-temps."

† Rosenmüller, Icones Chirurgico-Anatomicæ. Wiemar, 1805. See also Mackenzie in Medical Gazette, vol. xi.

perior fork, however, has a few of its fibres blended with the ciliaris."

The action of the muscle appears to be to direct the lacrymal papillæ and points in towards the lacus lacrymalis, and to assist in keeping the edges of the eyelids properly adjusted to the eyeball.

Nerves.—The parts of the organ of vision which have been just described receive their nerves from the fifth and seventh pairs; the former communicating sensibility, the latter the power to move. See articles, FIFTH PAIR OF NERVES, and SEVENTH PAIR OF NERVES.

The first division of the fifth pair gives nerves not only to the accessory parts of the eye, but supplies also the eyeball; hence it is called ophthalmic. The second division of the fifth sends filaments to the lower eyelids.

Nerves from the first division of the fifth distributed to the accessory parts of the eye.—The first division of the fifth pair or the ophthalmic divides into three nerves, the *frontal*, the *nasal*, the *lacrymal*.

1. *Frontal nerve.* The *supra-trochlear* branch of this nerve gives filaments to the upper eyelid and inner canthus. The continuation of the frontal nerve sends filaments to the upper eyelid and external canthus.

2. *Nasal nerve.* The *infra-trochlear* branch of this nerve supplies the parts at the inner canthus, the conjunctiva, the lacrymal caruncle and lacrymal sac; it also gives filaments to the orbicularis palpebrarum. The tensor tarsi* receives two twigs from it. The infra-trochlear sends branches upwards, which anastomose with those of the supra-trochlear.

3. *Lacrymal nerve.*—After supplying the lacrymal gland the branches of this nerve emerge from it, and ramify in the conjunctiva, orbicularis muscle, and skin of the eyelids. The lacrymal nerve forms anastomoses with other branches of the fifth.

Nerves from the second division of the fifth pair distributed to the accessory parts of the eye.—The principal of these is the *inferior palpebral* branch of the infra-orbital. The inferior palpebral nerve divides into two branches, an external and an internal, which indeed may be separate from the first.

The external branch runs in the substance of the lower eyelid, distributing branches in its course, to the outer canthus, where it anastomoses with the inferior palpebral filaments of the lacrymal nerve.

The internal branch supplies the part of the lower eyelid towards the nose, and terminates in the parts at the inner canthus, anastomosing with a branch of the infra-trochlear.

The facial or portio dura of the seventh pair.—Of the accessory parts of the eye, the orbicularis muscle is that which receives branches from the portio dura of the seventh pair; perhaps, also, the tensor tarsi muscle, as Mackenzie conjectures. These branches of the portio dura freely anastomose with the branches of the fifth pair above described.

To this superficial notice of the nerves of the accessory parts of the eye described in this article, all that requires to be added is, that the levator palpebræ superioris receives its nervous filaments from the third pair.

Bloodvessels.—1. *Arteries.*—The branches of the external carotid ramified on the face and the ophthalmic artery from the internal carotid are the sources from which the accessory parts of the eye receive their arteries.

The branches of the external carotid in the face, viz. the facial, the infra-orbital of the internal maxillary, the transverse artery of the face and the temporal send ramifications to the eyelids. Towards the inner canthus the facial ends in the *angular artery*, which anastomoses with the nasal branch of the ophthalmic. The angular artery, or some one of its branches, is implicated in the operation for fistula lacrymalis as it is called.

The ophthalmic artery gives off the *lacrymal*, usually one of its first branches after its entrance into the orbit. The lacrymal supplies the upper and lower masses of the lacrymal gland, besides other parts in the orbit, and at last issues from that cavity at the external angle of the eye. The muscular arteries of the ophthalmic, after supplying the recti muscles, are continued forward on the front of the eyeball—one from the external rectus muscle, and two from each of the other recti. These arteries divide into two sets of branches, of which one set ramify in the ocular conjunctiva, and the other set supply the sclerotica.

The ophthalmic, as it issues from the orbit at the internal canthus, gives off the *palpebral arteries, superior* and *inferior*. These ramify, in their respective eyelids, towards the external angle, where they meet and inosculate with the terminating branches of the lacrymal artery. The superior palpebral artery, moreover, inosculates with the supra-orbital and anterior temporal; the inferior palpebral artery with the nasal branch of the ophthalmic, the infra-orbital and transverse artery of the face, thus forming the *tarsal or palpebral arches*.

The ramifications sent, from the branches of the external carotid in the face, to the eyelids, and those from the ophthalmic, form by their inosculations a network, from which are supplied the different structures of the eyelids, the conjunctiva, the lacrymal caruncle, and the lacrymal sac.

Where the ocular and palpebral portions of the conjunctiva run into each other, bloodvessels from the muscular enter and subdivide into two sets of branches—one set smaller, to the ocular conjunctiva, the other set larger, to the palpebral conjunctiva. The latter receives another and a still larger set, which enter it at the orbital margin of the tarsal cartilages, anastomose with the first set, and ramify forwards to the free margin of the eyelids.

The bloodvessels of the ocular conjunctiva are few and small in comparison to those of the palpebral. They affect a reticular arrange-

* Rosenmüller, Icones chirurgico-anatomicæ. Weimar, 1805.
Trasmondi, Intorno la Scoperta di due Nervi dell' Occhio umano ragguaglio. Estratto dal Giornale Arcadico, t. xix. p. 1. Roma, 1823.

ment, produced partly by the vessels crossing over each other simply, and partly by inosculations. The latter is particularly the case around the cornea. It is only in the inflamed state—in catarrhal ophthalmia—that the vessels of the ocular conjunctiva can be well seen. In catarrhal ophthalmia, large superficial tortuous vessels are observed proceeding in a direction towards the cornea; a few of the same size are seen crossing these, especially at a distance from the cornea. Underneath the large vessels is a network of smaller ones, the branches of the larger. The arrangement of the vessels around the margin of the cornea has been already noticed. It can scarcely be doubted that the large dark-coloured varicose vessels, derived from the muscular, seen in the conjunctiva in the so-called arthritic states of the eye, are veins, as also the largest and most tortuous of those seen in catarrhal ophthalmia.

Of the two sets of vessels distributed to the conjunctiva, one set supplies the conjunctiva forming the palpebral sinuses, the other that part of the conjunctiva which corresponds to the tarsal cartilages. Both sets give off numerous branches, which subdivide very minutely in the papillary body. The second set, after having given off their ramifications to the papillæ, proceed towards the margins of the eyelids; following, in the upper, a straighter and more parallel direction than in the lower.

2. *Veins.*—The veins from the eyelids discharge their blood into the anterior and posterior facial veins.

The blood from the other accessory parts of the eye is returned to the cavernous sinus by the ophthalmic veins, of which there are two to each eye:—one called the *cerebral ophthalmic*, and the other the *facial ophthalmic vein.*

Cerebral ophthalmic vein.—Larger than the facial ophthalmic vein, this begins at the inner angle of the eye, from the upper end of the anterior facial vein. From this it passes backwards through the orbit to the inner part of the superior orbital fissure, by which it enters the cranium, where it empties itself into the cavernous sinus—seldom into the circular sinus. In this course it has several communications with the facial ophthalmic. The cerebral ophthalmic vein receives directly or indirectly, besides the veins from the different parts of the eyeball and its muscles, a vein from the lacrymal sac, and from the parts lying at the inner canthus; the anterior nasal vein, the lacrymal vein, and the posterior nasal vein.

Facial ophthalmic vein.—This receives the infra-orbital and some other deep veins of the face, besides some veins from the eyeball. The deep branch of the anterior facial vein takes one of its origins from it. The facial ophthalmic vein leaves the orbit by the superior orbital fissure, and opens into the cavernous sinus below the cerebral ophthalmic.

Comparative anatomy and development.—In the description just given of the accessory parts of the human eye, allusion has been occasionally made to their structure in the lower animals; here such further observations will be offered as may tend to illustrate their physiological importance in the animal series.

And first, it may perhaps be well to keep in mind that, although generally speaking, organs, traced from the higher to the lower animals, are observed to become depreciated in development; still that this is by no means always the case in a ratio corresponding to the position of the animal in our classifications. For the circumstances connected with the mode of life of an animal, be it mammal, bird, reptile, or fish, may be such as to call for a greater or less development of some particular organ. Thus, though in the mammifera we find the eyelids very perfectly developed, and in fishes in an extremely imperfect state, or entirely wanting, and though we find gradations between these two extremes in the animals holding an intermediate place, still there exist mammiferous animals in which the integument passes right over the eyeball without forming any palpebral fold; and there are fishes in which there are not only palpebral folds, but also an orbicular muscle. Again, the semilunar fold of man and the higher quadrumana is enlarged in quadrupeds into the membrana nictitans, and in birds forms the very artificially constructed third eyelid, which subsists, though in a less perfect state, in reptiles, but in fishes, where the structure does exist, it is found again reduced to a semilunar fold. In man the lacrymal gland is large. In the lower mammifera generally, in birds, and in the higher reptiles the lacrymal gland is also found. But it is small in proportion to another gland situated at the nasal canthus of the eye, the glandule of Harder, which is developed in a direct proportion with the membrana nictitans, or third eyelid, and to which it therefore belongs. In man and the quadrumana there is no trace of the glandule of Harder. It is incorrect to view the lacrymal caruncle in that light, for both may exist together.

Besides these differences in the development of the accessory parts of the organ of vision observed in the animal series and capable of being generalised, there exist specific and individual differences which can only be noticed in detail.

1. *Eyelids.*

In subterranean mammifera, as the blind rat, the chrysochloris of the Cape, the common mole; among reptiles, in the pipa, which lives in obscure places; and in perennibranchiate batrachia, which inhabit subterranean lakes or marshes, as the proteus and syren; and in fishes which burrow in the mud or sand, as the anguilliform and certain cyclostomatous fishes, the eyes are very small, and the common integument passes right over them without forming any palpebral fold. In the Ophidian reptiles as first pointed out by Jules Cloquet; in Geckoes among the Saurian reptiles, as shewn by J. Müller; and even in the blind rat, according to the latter author, there is a compounding of the simple continuation of the integuments over the eyeball, as described above, with the existence of a conjunctiva underneath, enclosing an oculo-palpebral space. This structure will be described in speaking of the conjunctiva. In birds there is no example of the eyeball being covered over in a similar manner by a continuation of the skin.

In man the upper eyelid is the more developed and the more moveable. Descending from him the lower is found gradually to assume the superiority in this respect. In the cetacea the upper and lower eyelids are tumid folds of skin enclosing fat, but no tarsus, and the Meibomian glands are entirely wanting. There is no orbicularis palpebrarum muscle, but muscular fibres proceed from the anterior and posterior end of the orbital process of the frontal bone to the eyelids in the region of the outer and inner canthi. Instead of the levator palpebræ superioris there is a hollow conical muscle which arises from the circumference of the foramen opticum and terminates in the eyelids. A similar in four divisions occurs in the seal.* In the echidna there is a circular eyelid. In birds the lower eyelid is in general very much larger and more moveable than the upper. In the ostrich and some parrots both eyelids are equally moveable.

In birds the eyelids are closed in death. In the gallinaceous birds which I have examined this appears to be owing to an expansion of elastic membrane attached to the margin of the orbit and interlaced round the eyelids. During life the lower eyelid is opened by muscular action by a proper *depressor* muscle. The upper eyelid retains its levator. There is a tarsal cartilage in the lower eyelid; in the upper eyelid there is a less dense fibrous structure. The skin of the lower eyelid is naked and finer than that of the upper in accordance with its greater mobility.

In chelonian reptiles the lower eyelid is, as in birds, the larger and more moveable; and as the more moveable the eyelid the finer the integument, so in them the lower eyelid is naked as in birds.

In lizards the eyelids form a sort of sheet stretched before the eyeball with a horizontal fissure closed by a circular muscle and opened by a levator and depressor. In the chameleon the palpebral fissure is represented by a small hole opposite the pupil. Tracing the eyelids in a general way from batrachian reptiles to fishes, we find a gradual depreciation of structure; thus salamanders have two folds of skin, upper and under, for eyelids, but not sufficient to cover the eyeball, whilst the pipa has none. In fishes generally, the skin before passing over the front of the eye becomes finer and forms a slight circular fold, often only well-marked above. Sometimes there is an anterior and a posterior semilunar fold, as in the herring, salmon, but especially in several of the shark tribe. It is the Orthagoriscus mola which has circular folds for eyelids, and an orbicular muscle for closing them. The eyelids are again opened by five radiating muscles.

* Rapp, Die Cetaceen Zoologisch-anatomisch dargestellt, Stuttgardt and Tübingen, 1837, quoted from Müller's Jahresbericht, p. cxx. in Archiv, 1838.

Among the invertebrata some of the cephalopoda have large palpebral folds. In the octopus "the eyes are small in proportion, and the skin is drawn over them so as to cover them entirely at the will of the animal."* There are no eyelids in the sepia officinalis, but a continuation of the integuments passes over the eye.

Eyebrows and eyelashes occur only in a few mammalia. Eyelashes exist in the pachydermata, ruminants, &c. but are wanting especially in small mammals. Meibomian glands are commonly found.

In birds the eyelids sometimes present cilia. This is the case only in some birds of prey, in some parrots, in the ostrich, &c. but seldom in other orders. Very small Meibomian follicles are said to exist in the eyelids of birds. In the eyelids of a common fowl at present before me, there are small transverse fissures on the margin of the lids filled with a sebaceous matter. They have the appearance of very small Meibomian glands, not closed as in the mammifera, but open along their whole length.

In a preceding part of this article I remarked on some points of resemblance between the iris and eyelids, as regards functions, and sympathy in the performance of those functions. In some of the lower animals there are certain points in which they even approximate in form. In connexion, therefore, with the subject of the eyelids it will not be out of place to allude to that flocculent growth of the uvea hanging from the upper margin of the iris over the transversely elongated pupil in the horse, &c. and which appears to serve the purpose, if it may be so expressed, of an internal eyelid. An analogous but more curiously and highly developed structure—a blending as it were of the iris with some remains of the structure of the eyelids—exists in the eyes of several fishes; among others in the skate.

The structure alluded to is a digitated extension of the whole substance of the upper part of the iris, hanging over the pupil, which it is large enough entirely to cover. There being no intrinsic power of motion in the iris of fishes, the mechanism by which this digitated veil is drawn up from over the pupil is this:—Where the upper part of the ciliary margin of the iris is connected with the sclerotica, the latter is very flexible and is externally intimately connected with a fold or rudimentary eyelid which the integument forms before passing as conjunctiva over the eye. Muscular fibres are inserted into this fold at the point of connexion, and draw it upwards; the flexible part of the sclerotica of course follows this movement and the upper part of the iris, the sclerotica, so that the digitated veil is drawn up from over the pupil. In a young skate which I removed from the egg and preserved alive for some weeks, I observed that the digitated veil was kept down during the day, but was drawn up toward evening, and the large black pupil exposed.

* Cuvier, Regne animal, vol. iii. p. 12, Paris, 1830.

2.—*The conjunctiva.—Semilunar fold, membrana nictitans or third eyelid.—Lacrymal caruncle and glandule of Harder.*

The existence of eyelids supposes a conjunctiva,—that is, the integument modified into a mucous membrane lining the posterior surface of the eyelids, covering the front of the eyeball, and thus connecting these two parts together. In those animals in which there is no palpebral covering either in the usual form of eyelids, or in that anomalous form in which there is no palpebral opening, there is, properly speaking, no conjunctiva: at the most, the common integument may be softer, thinner, and more transparent where it covers the eye.

The points deserving particular notice in the comparative anatomy of the conjunctiva are,

1. The oculo-palpebral space of the conjunctiva.

2. The membrana nictitans and third eyelid, with the glandule of Harder.

In most animals the oculo-palpebral space of the conjunctiva is as it has been described in man. Serpents have been generally regarded as being without eyelids and viæ lacrymales. The eye, indeed, has been commonly described as covered by a transparent lamella of epidermis, which is cast with the rest of the epidermis; and this has been often adduced as an argument in favour of the extension of the conjunctiva over the cornea in other animals. Serpents have a palpebral covering, a conjunctiva and viæ lacrymales; but the conformation of these parts is quite peculiar. For the first true exposition of the point we are indebted to Jules Cloquet.*

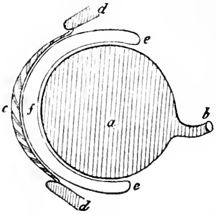
In the article Hearing, Organ of, at the end of the section on the parallel between the ear and the eye, it is said, "A part in the composition of the appendages of the eye analogous to the membrana tympani is only to be conceived by supposing the existence of a *mediate anchylo-blepharon*, that is, an irregular membrane stretched between the edges of the eyelids, uniting them together, and closing in the space lined by the conjunctiva, which space would now communicate with the exterior only by the lacrymal canalicules and nasal duct, in the same way that the tympanic cavity communicates with the exterior only by the Eustachian tube." The *mediate anchylo-blepharon* here *supposed* is the *actual* and *regular structure* in serpents, and is the sole cause of the apparent anomaly in the conformation of their eye appendages. The structure is this:—

Around the margin of the orbit the skin appears as if it formed a palpebral fold, covered with scales, and representing a sort of frame, in which is set, as it were, a transparent continuation of the skin before the front of the eye. But this is not the conjunctiva; it is a *natural mediate anchylo-blepharon*, or a palpebral covering without palpebral fissure. It is, however, transparent, and was therefore formerly confounded with the cornea. A conjunctiva lines the inner surface of this palpebral covering without palpebral fissure, and invests the greater part of the orbital cavity, from which it is reflected on the sclerotica, and is from thence continued over the cornea, closely adhering to it.

* Memoire sur l'Existence et la Disposition des Voies Lacrymales dans les Serpens. Paris, 1821.

The conjunctiva thus forms a sac (called by Jules Cloquet oculo-palpebral sac of the conjunctiva), confining a space (which may in like manner be called oculo-palpebral) into which open the excretory ducts of the lacrymal gland. From it the tears are drawn off by a canal between the jaw and palate bone into the mouth, of which more will be said farther on.

Fig. 17.



Vertical section of the eye of the common viper, to show the disposition of the conjunctiva. (From Jules Cloquet.)

a, the eyeball; *b*, the optic nerve; *c*, the eyelid; *d, d*, the scales surrounding the eyelid, and into which it appears as if enchased; *e, e*, folds and culs-de-sac formed by the oculo-palpebral conjunctiva on being reflected from the orbital cavity upon the eyeball; *f*, cavity of the oculo-palpebral sac of the conjunctiva.

From the above description it will be readily understood how it is from the palpebral extension of the skin that the epidermis falls when the skin is said to be cast, and not from the conjunctiva.

Muller* has found the above structure in all true serpents, even in the amphisbœnæ, whose eyes are covered with thick skin. I do not know if it has been observed in cœciliæ also. He has found a similar structure among the saurian reptiles in the geckoes, even in the genus phyllurus. He has even found it in a mammal, spalax typhlus,† the eyes of which appear to be covered by the thick hairy skin, underneath which, however, there is a small sac of conjunctiva. In the chameleons, which follow the family of the geckoes, in Cuvier's arrangement, there is a near approach to the same structure, the palpebral covering presenting only a very small palpebral opening opposite the pupil.

The membrana nictitans and third eyelids.—In the quadrumana, as in man, the conjunctiva forms at the nasal canthus a simple semilunar fold, but larger. In the other mammifera, including the herbivorous cetacea, and ex-

* Ueber eine Merkwürdige Eigenthümlichkeit im Bau der Augen und Thränenwerkzeuge bei den Geckonen. In Ammon's Zeitschrift, Bd. i. p. 179.

† Handbuch der Physiologie des Menschen, Zweiten Bandes Zweite Abtheilung, S. 313. Coblentz, 1838.

cepting only the true cetacea, this fold is developed into the membrana nictitans, which is disposed vertically within the horizontal eyelids at the nasal canthus, and is capable of being pushed more or less towards the temporal canthus, over the front of the eyeball.

The membrana nictitans derives firmness from a thin plate of cartilage, which has sometimes a sort of pedicle passing backwards by the inner side of the eyeball. In the sheep, for example, the cartilage of the membrana nictitans is of the shape of the letter T. The cross top forms the margin of the membrane; and the leg, closely embraced by the glandule of Harder, extends backwards between the eyeball and inner wall of the orbit. The cartilage of the membrana nictitans, unlike the tarsal cartilages, is true cartilage, with nucleated corpuscles.

In the elephant it is said there is a muscular arrangement for carrying the membrana nictitans outwards over the front of the eyeball. I think I have observed in the rabbit that the membrana nictitans receives part of the expansion of the levator of the upper eyelid. The membrana nictitans has not, however, like the third eyelid of birds, any proper muscular apparatus; and when it is moveable, the motion is produced by the eyeball, on its being retracted deeper into the orbit by the retractor muscle, which displaces and presses forwards the cartilaginous pedicle above described.

The structure called semilunar fold in man, and membrana nictitans in quadruped mammifera, has attained its greatest development in birds, in which it is called the third eyelid. It is transparent and capable of covering the whole front of the eyeball. Enclosed in the conjunctival reduplication there is a fibro-cartilaginous structure, very thin and membranous. Of a triangular form, the third eyelid has its free margin oblique from above downwards, and from without inwards. In the state of repose it is retracted and folded vertically in the nasal angle of the eye. The third eyelid is drawn over the front of the eye by a very peculiar mechanism consisting of two muscles, the slender tendon of one of which runs through an elongated loop in the broad free end of the other. This muscular apparatus is supplied by the nervus abducens.

The *quadratus* is a broad thin trapezoidal muscle. It arises from the upper and posterior part of the eyeball, behind the prominence of its largest circumference. From this point its fibres, which form a thin but broad fleshy belly, descend towards the optic nerve, converging somewhat. It then terminates abruptly in a free tendinous margin, close to the upper part of the optic nerve. In this free tendinous margin, which is considerably narrower than the origin, there is an elongated loop or canal, in which the tendon of the other muscle plays.

Pyramidalis muscle.—The fleshy part of this muscle is comparatively smaller. It arises by a broad curved base from the lower part of the eyeball, opposite the preceding. In its ascent towards the optic nerve, the muscle becomes contracted, and at last ends in a slender tendon on the nasal side of the optic nerve. The tendon immediately enters the pulley-canal in the extreme margin of the quadratus, and in traversing it turns round the upper part of the optic nerve. Thus changing its original direction, it passes downwards on the temporal side of the optic nerve to the lower part of the eyeball, round the prominent circumference of which it turns to get to the front of it, when it immediately enters the lower angle of the third eyelid. Having entered, it divides into two parts, one of which expands and runs between the layers of conjunctiva, forming the third eyelid, to the nasal angle of the eye; the other passes along and forms the pretty firm free margin of the eyelid in question. Having traversed the whole margin of this and arrived at the upper part of the eyeball, it is inserted into the sclerotica just at the middle of the line whence the *quadratus* derives its origin. It is by this arrangement that the superior angle of the third eyelid is attached to the sclerotica, and consequently rendered immoveable.

By its own elasticity the third eyelid remains retracted at the nasal angle of the eye. In this state its tendinous margin is relaxed; but when the two muscles just described contract, the tendon of the pyramidalis is drawn straight, and the third eyelid is thus stretched over the front of the eye.

"From this curious disposition of the muscles," says Dr. Porterfield,* "it is easy to conceive, how this internal eyelid is extended over the cornea far enough to cover all the pupil, though the muscles themselves are contained in a small space. Every body knows, that the contraction of all muscles is only in a certain given proportion to their length; and therefore that the eyelid might be drawn far enough over the cornea, nature was obliged to make use of a long muscle, which could not be contained in so small a place as the orbit, without being bent or inflected; and therefore the one muscle is bent upwards near the optic nerve, making an acute angle, where it passes through the perforated end of the other muscle, by which means its action is greatly increased. But its action is yet more increased by the contraction of the square muscle itself, which must draw the cord or tendon of the pyramidal muscle which passes through it, through a space double of what it moves itself; and thus the membrana nictitans is extended far enough to cover the whole cornea though its muscles are contained in a small space."

In Owls Nitzsch discovered a small bone on the lower surface of the bony ring of the sclerotica, *ossiculum tuberculare*, for the support of the long tendon of the pyramidalis. In parrots the third eyelid is small.

Among reptiles there is in chelonia and lizards a third eyelid much the same as in birds, but smaller and less moveable. It is moved only by a single muscle analogous to the pyramidalis of birds. "An allied structure," says Müller, "is a spectacle-like transparent part in the lower eyelid of some lizards,

* On the Eye, vol. i. p. 34. Edinburgh, 1759.

as several scinci, which may be drawn over the eye without interrupting vision, the cornea corresponding to it." This is the structure in the frog; for what Cuvier admitted as a third eyelid is horizontal instead of vertical, and, as Carus has shown, nothing more than the lower eyelid. In the frog the upper eyelid follows the motions of the eyeball. The lower eyelid has independent motion; admitting of being drawn over the eye and falling into a fold when this is open.

The anterior and posterior semilunar folds in certain fishes have been already alluded to.

The glandule of Harder.—The glandule of Harder belongs peculiarly to the membrana nictitans or third eyelid; it therefore does not exist in man and the quadrumana. The lacrymal caruncle is not the representative of it, as is asserted in Dr. Grant's Treatise on Comparative Anatomy, for both may exist together. I do not even know if it is correct to say that the two structures are developed in an inverse ratio, for in the sheep, in which the glandule of Harder is of considerable size, the caruncula is absolutely as great, if not greater, than that of man. Even among the hare kind, which have the membrana nictitans and glandule of Harder much developed, I find, particularly in the rabbit, a trace of lacrymal caruncle as scattered follicular grains along with small hairs at the inner canthus. It is only in birds that we lose all trace of the lacrymal caruncle.

The glandule of Harder is situated in the orbit between its inner wall and the globe of the eye. In the sheep, for instance, the glandular substance is collected around the cartilaginous pedicle of the membrana nictitans, on the inner surface of which it opens by two or three small ducts. In the elephant, in which the lacrymal gland is said to be wanting, or very small, the glandule of Harder is said to be very large. It opens between the membrana nictitans and the eyeball by an opening the size of a quill. In the hare kind, as has been said, the glandule of Harder is immense. It presents two lobes, and its duct opens in a wide lacuna within the membrana nictitans. According to Müller,* the elementary particles or ends of the ducts are minute vesicles everywhere equal and joining in the manner of branches into irregular oblong lobes. The excretory duct at the external surface of the gland opposite the eye is divided in the bilobated glandular mass into a great number of smaller ducts, which divaricating are joined each to a branch of the lobules.

In birds the glandule of Harder is commonly much more considerable than the lacrymal gland. It lies as usual at the nasal canthus and opens within the third eyelid towards the eyeball. There is never any caruncle. Müller tells us the glandule of Harder in birds is easily injected with mercury after its secretion has been all pressed out. The surface of the organ is divided into many smaller lobes. The internal ramification of the ducts does not appear to be complicated.

* De glandularum secernentium penitiori structura, p. 51, tab. v. fig. 6 and 7.

In reptiles the glandule of Harder is smaller than the lacrymal gland.

The secretion of the glandule of Harder is a thick transparent viscid matter.

III. *Secreting and derivative lacrymal apparatus.*—The development of the lacrymal gland and of that of Harder is generally in an inverse ratio. It would appear that the derivative lacrymal apparatus is more in relation with the lacrymal gland than with the glandule of Harder, as it is much developed in man, in whom there is no glandule of Harder, and, as is reported, it is wanting in the elephant, in which the glandule of Harder is said to be very large. The lacrymal gland exists in man, apes, sapajous, and snakes, but no glandule of Harder. In all other mammifera there is both a lacrymal gland and a glandule of Harder. In proportion as the latter enlarges the former becomes smaller. Among the cetacea, the dolphin possesses a lacrymal gland which surrounds the eyeball like a ring. Its excretory ducts, which are numerous, open on the inner surface of both upper and lower eyelids. The derivative lacrymal apparatus is wanting; in this respect, seals and walrusses agree with the cetacea.* Other mammals, as moles and shrewmice, are said to present no trace of lacrymal apparatus. In the elephant, small glandular grains the size of a pea are said to represent the lacrymal gland. Camper says the hippopotamus has no puncta, from which may be inferred the absence of any lacrymal passage into the nose. The elephant is also said to want the derivative lacrymal apparatus.

In birds the lacrymal gland is small, and lies at the posterior angle of the eye, either towards the roof or the floor of the orbit. The derivative lacrymal organs in the common fowl, for instance, consist of two large lacrymal points, the upper the larger, and a membraneous canal leading into the nose.

In reptiles, the lacrymal gland lies behind the eyeball, and is of considerable size, especially in harmless serpents. According to Duverney, the lacrymal gland in one species of typhlops is six times larger than the extremely diminutive eyeball; but even in poisonous serpents, the viper for instance, it is large.

The sauria and chelonia have for the most part both a lacrymal gland and a glandule of Harder, the former the larger. Batrachia want the lacrymal apparatus.

In serpents the secretion of the lacrymal gland is poured into the oculo-palpebral space, from which a lacrymal duct leads. In the colubri there is, in the fore and lower part of the oculo-palpebral space, a hole or round pore, in some individuals seen with difficulty, very distinct on the contrary in others, and which may admit a bristle. This is the lacrymal point; it is single and is continuous with a very slender membranous duct, semi-transparent, which forms the lacrymal canal. This, in harmless serpents, opens into a large pouch communicating with the mouth in front

* Rapp. l. c. Rapp describes, in the Cetacea, scattered grains of lacrymal gland, which open on the conjunctiva near the eyeball.

of the palatine branch of the upper jaw. Cloquet* calls this pouch intermaxillary sinus or sac. In venomous serpents, the lacrymal canal opens, as in the mammifera, in the external wall of the nasal fossæ.

There is no lacrymal apparatus in fishes.

In the description of the lacrymal gland in man, the intimate structure of it in the lower animals has been already alluded to. The remark of Müller may be repeated here, that similar glands have often a perfectly different structure in different animals; of which the lacrymal gland examined in the chelonia, birds, and mammifera affords an example.

The lacrymal bone contributes to separate the orbit from the cavity of the nose. It is wanting in certain mammifera, as the phocæ and most cetacea. It is enormously developed, on the contrary, in certain others, as the giraffe, stag, &c. It exists also in birds, and forms in them often the greatest part of the inferior margin of the orbit. In reptiles, its existence is variable. It is found in crocodiles. It is absent in the chelonia, ophidia, and batrachia. It is also wanting in fishes, unless the first infra-orbital be assumed as analogous to it.

In ruminating animals, remarkably so in deers and antelopes, the infra-orbital fossa of the superior maxillary bone is very large, and is lined by a reflection of the skin, more or less in the form of a sac. The skin, which has assumed the characters of a mucous membrane, contains in its substance numerous follicles, which secrete a thick blackish unctuous humour—a secretion which appears to have some relation with the sexual function. This matter has been improperly called *tears*, hence the French name *larmiers* of the infra-orbital glandular sacs of ruminants. In the sheep these organs are represented by a mere fissure extending on the side of the nose from the nasal canthus. Meckel compares to this structure the foveæ in the face, behind the nostrils, of several poisonous serpents, such as the rattle-snake; but the membrane lining these parts scarcely appears to secrete anything. The temporal gland of the elephant seems to be of the same nature as the infra-orbital glandular sacs of ruminants.

Development of the accessory parts of the eye.†—The accessory parts of the eye appear subsequently to the eyeball, and, as is the case with the accessory parts of the organ of hearing in reference to the labyrinth or ear-bulb, have quite a separate and distinct origin from it. That the development of the accessory parts of the eye is independent of that of the eyeball is confirmed by the anomalous conformation which the organ has been sometimes found to present; thus Malacarne relates a case in which the eyeballs, their nerves and muscles were wanting, whilst the lacrymal apparatus and eyelids were regularly developed.

Up to the eighth week the external integument passes quite smoothly over the eyeball. The conjunctiva is then partitioned off by the formation of a linear fold, which, in the ninth week, surrounds the anterior surface of the eyeball like a small ring. The upper and lower parts of the fold progressively enlarge until they meet each other over the eyeball, which takes place about the twelfth week.

The progress of the development of the eyelids is sometimes arrested, so that mere folds of skin have been found occupying their places, or, development having proceeded a little further, the eyelids have been found presenting their regular conformation indeed, but too short to cover the eyeball and incapable of motion.

Having met, the edges of the eyelids adhere by the extension of the epidermis from the one to the other. In the human embryo the adhesion between the eyelids by the extension of the skin ceases towards the latter months, but the edges continue sticking together by the Meibomian secretion until the period of birth. In the young of several of the mammifera, as the carnivora and rodents, the eyelids continue closed for some time after birth—from one to two weeks. In birds, even in the embryo state, the eyelids never unite.

Sometimes adhesion between the eyelids in the human subject is found at birth, constituting what is called *congenital anchyloblepharon;* and this may be either immediate or by the intervention of a membranous structure.

The closure of the pupil by the pupillary membrane in the fœtus corresponds to the adhesion of the eyelids to each other at that period. According to Meckel the pupillary membrane continues entire in animals born blind, as it is expressed, as long as the eyelids remain closed.

The tarsal cartilages first appear distinctly in the fifth month; and at birth, that of the upper is perfectly developed. The eyelashes first appear free about the sixth month.

The lacrymal gland is already evident in the last half of the fourth month.

The inner canthus of the eye is at first more elongated than it is afterwards.

On the first appearance of the eyelids, Burdach tells us, the lacrymal caruncle presents itself; and at the inner angle a diverticulum of the conjunctiva sinks down to the oro-nasal cavity as the commencement of the lacrymal sac and nasal duct. The lacrymal points project very much in the fifth month, and in the seventh are somewhat more retracted. The lacrymal apparatus in general, as also the Meibomian follicles, are proportionably much developed at an early period.

BIBLIOGRAPHY.—See that of article EYE and the several works referred to in the course of this. The most complete, indeed, so far as I know, the only monography, is that of John Christian Rosenmüller, "Partium externarum oculi humani imprimis organorum lacrymalium descriptio anatomica, iconibus illustrata." Lipsiæ, 1810. In this will be found a catalogue raisonné of all preceding works bearing on the subject.

LARYNX. Syn. Gr. λαρυγξ, from λαρυγγιζω (clamo); Fr. *Larynx*; Germ. *Kehlkopf*; Ital. *Laringe.*—The larynx is a complex piece of mechanism resembling a kind of box, (*pixis cava,*) composed of an assemblage of cartilages, the density and elasticity of which serve to protect its more delicate tissues, and to allow the free transmission of air for respiration. It is also exquisitely adapted for the production of voice.

The larynx is situated in the mesial line, and opens superiorly into the pharynx, and inferiorly into the trachea. It occupies the anterior superior part of the neck, immediately below the os hyoides, and before the pharynx, which lies between it and the vertebral column. In front it is very superficial, being covered only by the sub-hyoidean muscles, and the common integuments.

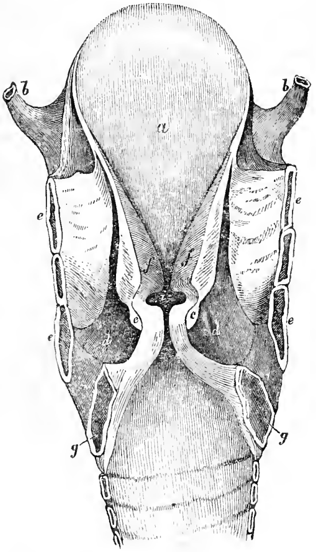
It admits of various kinds of motion: 1, those of elevation and depression parallel to the long axis of the body; 2, those complex movements within it which take place during respiration and the production of vocal sounds.

The larynx considered with reference to the trachea, presents an enlargement denominated the *caput asperæ asteriæ*, or the head of the trachea. The absolute volume of the larynx varies with the age and sex of the individual: its magnitude is much more considerable in men than in women; in the former it acquires an extraordinary developement at the age of puberty. In eunuchs, however, this enlargement does not take place.

The larynx does not represent any regular geometrical figure; it may be defined as an irregular, inverted, truncated cone, whose sections at the apex and base are elliptical, but approaching nearly to a circle at its junction with the trachea.

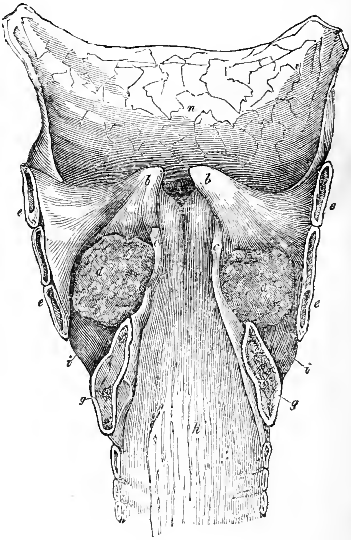
This organ is perfectly symmetrical, which, however, applies to one of its sections only, viz. that of its mesial plane, or axis major; consequently, all the others must be unsymmetrical: the section made at right angles to it, or in its axis minor, gives the relative situation of its internal mechanism, as in *figs.* 18 and 19, which should be carefully studied, with reference to the physiology of this organ.

Fig. 18.



The anterior transverse section of the larynx and trachea. *a*, the epiglottis; *b*, *b*, the horns of the os hyoides; *c*, *c*, the inferior thyro-arytenoid ligaments (chordæ vocales); *d*, *d*, the thyro-arytenoid muscles; *e*, *e*, section of the thyroid cartilage; *f*, *f*, the superior boundaries of the ventricles; *g*, *g*, section of the cricoid; *h*, the trachea; *l*, *l*, the ventricles.

Fig. 19.



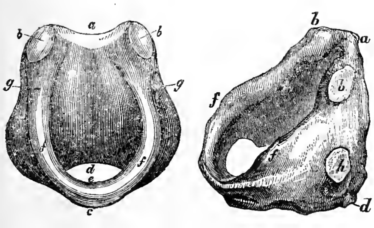
The posterior view. The letters *c*, *d*, *e*, *g*, *h*, represent corresponding sections of the same parts; *b*, *b*, the arytenoid cartilages invested by mucous membrane; *n*, the pharynx laid open.

The larynx is composed of several structures, which may be classed as follows: 1, the cartilages; 2, the ligaments; 3, the muscles; 4, the mucous membrane; 5, the mucous glands; 6, the arteries and veins; and, lastly, the nerves.

The cartilages of the larynx are nine in number,* of which three are single and unsymmetrical, the epiglottis, thyroid, and cricoid; two are placed laterally, and form a pair, called the arytenoids. Upon the summits of these are found two minute cartilaginous bodies, termed *cornicula;* the remaining two (which, however, are not always present) are situated anterior to the arytenoids, and involved in the aryteno-epiglottic folds, named the *cuneiform cartilages.*

The cricoid cartilage. Gr. κρικος, a ring, ειδος; Lat. *Cartilago annuliformis;* Fr. *Cricoïde* ou *annulaire;* Germ. *Ringknorpel;* Ital. *Cricoide.*—This cartilage, situated at the base of the larynx, which it supports, is the thickest and strongest of the whole assemblage of cartilages. It is connected to the first ring of the trachea by elastic ligaments and mucous membrane. Its form, that of a ring, is not quite circular, but approaching to an elliptical figure. It is shallow in front, at *c, e,* (*fig.* 20,) but it is thicker and deeper than the first ring of the trachea; and, posteriorly, it is considerably deeper than at its anterior part, in the proportion of eight to two and a-half.

Fig. 20.



A B

A, an anterior, B, the side view of the cricoid cartilage; *a,* the posterior superior margin; *b, b,* the crico-arytenoid articulating surface; *b, g, f, e,* the superior descending margin; *d, e,* the tracheal aperture of the cricoid; *a, d,* the greatest, *a, c,* the least depth of surface; *a, e,* the obliquity of the superior section to the axis; *h,* the left surface articulating with the inferior cornua of the thyroid cartilage.

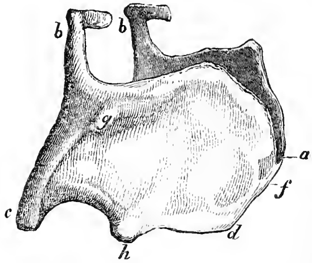
The anterior external surface gives attachment to the crico-thyroid muscles (see *fig.* 26); more posteriorly we find an apophysis for the articulation of the thyroid (*h, fig.* 20, B). Its posterior surface is divided into two equal portions by a vertical ridge along its middle line, *a, d, fig.* 20, B. This ridge, which was first noticed by Galen, gives attachment to some longitudinal fibres of the œsophagus. On each side of it a concave surface is observed, which gives origin to the crico-arytenoidei postici, *e, e, fig.* 27.

The internal surface is smooth, and lined by the mucous membrane of the larynx. The inferior margin is horizontal, and nearly circular; but the superior, which is bevelled obliquely inwards and upwards, about *c, e,* (*fig.* 20,) ascends backwards in the direction of *e, f, g, b,* (*fig.* 20,) being slightly curved downwards between *f* and *g.* The anterior superior outline of this cartilage presents that of the section of a cylinder, whose obliquity to its axis is in the direction *a, e,* and therefore is elliptical. It recedes anteriorly from the lower margin of the thyroid cartilage in the direction of *g, f, e,* (*fig.* 20,) leaving an interval called the crico-thyroid space, *a,* (*fig.* 20, B,) which is occupied by the crico-thyroid ligament; on each side, in the lines *e, f, g,* by the lateral ligaments, and more posteriorly by the crico-arytenoidei laterales, in the space *f, g,* to the external side of *b* (*fig.* 20).

The posterior superior margin is horizontal on each side of *a,* (*fig.* 20,) and parallel to the inferior at *d,* having at *b* and *b* an oblong, oblique, and slightly cylindrical surface, inclined upwards and outwards for the articulation of the arytenoid cartilages. These surfaces are considered by Willis as "portions of cylinders, whose axes are inclined both with respect to the horizontal and vertical sections." In the vertical section, the projection of this articulating axis is in the position G, C, (*fig.* 28,) and in the horizontal, in the line O, P, (*fig.* 30.) Between these surfaces is a slight depression for the insertion of the arytenoid muscles.

The thyroid cartilage. Syn. Lat. *Cartilago scutiformis;* Fr. *Thyroïde;* Germ. *Schildknorpel.*—This cartilage derives its name from θυρεος, a shield, and ειδος, form. It embraces the cricoid in a manner analogous to the carapax of the tortoise. It is formed to protect the internal mechanism of the larynx, both in front and at both sides, but is open behind. It serves

Fig. 21.



An angular view of the thyroid cartilage. *a,* the notch; *b, b,* the superior cornua; *c, c,* the inferior cornua; *g, g,* the superior tubercles; *h, h,* the inferior tubercles; *e, e,* the wings of the thyroid; *i, a, i,* the superior margin; *h, d, h,* the inferior margin; *a, d,* the mesial line; *f,* the pomum.

as a fulcrum and lever for the action of several muscles. It is composed of two quadrilateral laminæ uniting in front at the mesial line (*a, d,*

* Galen describes only three, χονδρος θυρεοειδης, χονδρος δευτερος, χονδρος αρυταινοειδης.

fig. 21): the angle of union becomes more acute as it approaches towards *d*. The prominence of this angle on the mesial line constitutes what is called the pomum Adami, which is more developed in the male than in the female sex, and becomes more conspicuous after the age of puberty; it may be readily felt in the living subject. On the four posterior angles of the thyroid are situated four cornua, or horns; two superior, *b*, *b*, and two inferior, *c c*, (*fig.* 21); they appear mere prolongations of the posterior margins; the superior being longer than the inferior are called the great horns; they are articulated to the os hyoides by ligaments, which allow a motion for the approximation and recession of the larynx to and from the os hyoides. The inferior horns are shorter, curved forwards, and articulated at their extremities to the cricoid by oblique planes, directed forwards and inwards. On each wing of the thyroid there are two tubercles, one on the superior, and the other on the inferior margin (*g*, *g*, and *h*, *h*, *fig.* 21). The superior tubercles are the largest. A small ridge passes obliquely across the external surface of the wings from *g* to *h*, extending from the base of one tubercle to the other, dividing each wing into two unequal segments, of which three-fourths are anterior and superior, and one-fourth posterior and inferior to the ridge. The anterior margin of the ridge gives attachment to the hyo-thyroid, and lies under the sterno-hyoid muscles, and the posterior to the inferior constrictor of the pharynx and sterno-thyroid muscles.

The posterior or hollow surface of the angle formed by the junction of the alæ of the thyroid gives attachment on each side of the mesial line to the thyro-arytenoid ligaments (*chordæ vocales*) and muscles. The wings are concave internally for the lodgement of the thyro-arytenoidei and crico-arytenoidei laterales muscles, and give attachment at their posterior margins to the membrane of the pharynx.

The superior margin of each wing is curved in the line *i*, *a*, *i*, (*fig.* 21,) and gives attachment in its whole length to the thyro-hyoid membrane: it is deeply notched at *a*, immediately above the pomum Adami. It is less deep, and more broad and round in women than in men.

Near the superior tubercles there is a notch, sometimes a foramen for the transmission of the superior laryngeal nerve. The inferior margin of the thyroid is nearly horizontal, and is shorter than the superior: there is a slight prominence at *a*, (*fig.* 21,) to which is attached the crico-thyroid ligament. Between the inferior tubercles at *h*, *h*, (*fig.* 21,) and the inferior cornua, the lower margin is arched rather deeply. The posterior surface and margin of the wings of the thyroid are ridged, and give attachment to several muscles; it rests against the vertebral column, which forms a base to the arc of the thyroid, and protects the internal structure of the larynx.

The arytenoid cartilages. Syn.: Gr. ἀρυταινοειδὴς, Galen; Lat. *Cartilagines arytenoideæ*; Fr. *Cartilages arytenoïdes*; Germ. *Giessbeckenknorpel.*—The arytenoid cartilages are two very irregularly formed bodies, situated on the articulating surface of the posterior, inner, and upper margin of the cricoid, (*b*, *b*, *fig.* 20,) in such a manner as to resemble the mouth of an ewer; hence their name. They may be considered of a triangular or pyramidal figure, having their bases spread out, (*a* and *a*, *fig.* 22,) and presenting surfaces for the attachment of ligaments and the action of muscles. We observe, 1, on their posterior aspect, triangular concave surfaces, between *f* and *e*, (*fig.* 22,) occupied by the oblique and transverse arytenoid muscles. 2. Anteriorly, convex, triangular surfaces, *d*, *b*, (*fig.* 22,) with

Fig. 22.

ridges, (*b*, *fig.* 27,) for the attachment of the superior thyro-arytenoid ligaments. 3. Laterally, cavities for the insertion of the thyro-arytenoid muscles, and lodgment of the cuneiform cartilages, (*g*, *fig.* 22). 4. Internally, surfaces reciprocally parallel, lined with mucous membrane, which permit their close approximation. 5. Bases, on which are oblique, curved, oval grooves, *a* and *a*, (*fig.* 22,) corresponding to the articulating surfaces of the cricoid; there are also on each of these bases two prominences, one lateral, (*c*, *fig.* 22,) which gives attachment (*l*, *fig.* 27,) to the crico-arytenoideus lateralis and posticus muscles; the other anterior, giving attachment (V, *fig.* 29) to the inferior thyro-arytenoid ligament. The latter prominence projects over the vocal tube one-fifth of an inch in the male, and one-seventh in the female. On the summit of the vertical prominences (*f*, *f*, *fig.* 22) is situated a small appendage called *corniculum laryngis*. The arytenoid cartilages have extensive freedom of motion, consisting of a rotatory, round the articulating axis of the cricoid, O, P (*fig.* 30); and a sliding motion, transverse to their axis of articulation about the point B (*fig.* 30).

The cornicula laryngis.—Syn. *Capitula Santorini*; *tubercles of Santorini*; *cartilagines corniculis*; *Santorinischer Knorpel*, Germ. These are two very small cartilaginous bodies first described by Santorini, from whom they derive their name. Their figure is nearly triangular with a flat smooth surface at their bases, articulated with some freedom of motion to the apices of the arytenoid cartilages. They lengthen the arm of the vertical lever of the arytenoid, and yield to any oblique force directed upon them.

The cuneiform cartilages, (Syn. *cartilagines cuneiformes, seu Wrisbergianæ*,) are two small cylindrical cartilaginous bodies, situated immediately in front of the vertical prominence of the arytenoid cartilages in the fold of mucous membrane *g*, (*fig.* 22.) They present a vertical and horizontal prominence in the shape of the letter L, and partake of the form of the arytenoid cartilages. They are not always present, and their existence in man is denied by Cruveilhier:* this however is an error. Both Cuvier† and Wolff‡ have confounded them with the cornicula or cartilages of Santorini. In the Quadrumana they are conspicuous, having the superior vocal ligaments attached to their bases, and they appear afterwards to connect them with the arytenoid cartilages. The cuneiform cartilages are sometimes described by Cruveilhier and other writers (though inaccurately) as the arytenoid glands. They serve as a link of connection between the arytenoid cartilages and superior ligaments.

The epiglottis, from ἐπι, upon, γλωττα, the tongue. Syn. κλῆθρον, Hipp.§ *Ligula*, Gal. *Operculum*, Cic.‖ *Cartilago epiglottidis. Epiglotte*, Fr. *Kehldeckel*, Germ. The epiglottis is a cartilaginous valve, situated at the base of the tongue, and covering the opening of the larynx. The direction of the epiglottis is vertical, except during the act of deglutition, when it becomes horizontal. In form it has been compared to a cordate leaf, (*fig.* 23,) or that of the artichoke. The dimensions vary with the volume of the larynx. The anterior aspect of the epiglottis is convex, the posterior concave; it is partly free and partly connected: the free portion projects above the level of the base of the tongue. It is lined by the mucous membrane: the centre of its superior margin is very slightly notched. Inferiorly it terminates by a kind of pedicle, very thin and delicate, which is attached to the angle of the thyroid immediately above the plane of the thyro-arytenoid ligaments. Numerous foramina are observed, perforating its substance (*f f*, *fig.* 23), rendering the structure of this cartilage less dense than that of the thyroid or cricoid cartilage. It is considered to be more brittle, in consequence of the cohesion of its particles being affected by these perforations. Its elasticity, however, is *augmented* by each perforation admitting some fasciculi of the yellow elastic ligament which is expanded, and, as it were, rivetted on its anterior aspect. In the larger Ruminantia, such as the ox, this structure is very conspicuous, the thickness of the elastic tissue being nearly equal to that of the epiglottis itself. This ligament is disposed so as to secure permanently the return of the epiglottis after its de-

Fig. 23.

pression in the act of deglutition, independently of any muscular fibres. Its perforations have been described as giving lodgement to "muciparous follicles," but their office seems not to have been hitherto thoroughly investigated.

Articulations and ligaments of the larynx.— The articulations are divided, first, into those connecting the larynx with surrounding structures, called extrinsic articulations; and, secondly, those peculiar to the larynx itself, termed intrinsic articulations.

Extrinsic articulations.— The hyo-thyroid

* Anat. Descript.

‖ De Nat. Deor. ii. p. 54.

articulation. The thyroid cartilage is united to the os hyoides by three ligaments: the middle and two lateral. 1st. The ligamentum thyro-hyoideum medium is a lax yellow tissue arising from the superior margin of the thyroid, and inserted into the inner margin of the os hyoides: it is thicker and denser at its middle part; its lateral borders are involved with the surrounding cellular membrane. The anterior surface in its middle is situated immediately under the integuments, having its sides covered by the thyro-hyoidei muscles, (*g, fig.* 25) and its posterior surface corresponding with the form of the epiglottis. 2d. The ligamenta hyo-thyroidea lateralia are small round ligaments on each side of the larynx, connecting the tubercles of the great horns of the os hyoides with the extremities of the superior cornua of the thyroid cartilage (*c c, fig.* 24). In the substance of these ligaments there are often found small osseous or cartilaginous bodies.

The articulations of the thyroid cartilage

Fig. 24.

with the os hyoides are furnished with synovial membranes.

The ligaments of the epiglottis.—The epiglottis gives attachment to three ligaments, which contribute to its elasticity and the stability of its position.

1. The *ligamentum thyro-epiglottideum* arises from the mesial line below the notch of the superior angle of the thyroid, and is inserted into the base of the epiglottis. It binds the epiglottis to the thyroid cartilage. 2d. The *ligamentum hyo-epiglottideum* arises from the inner surface of the base of the os hyoides; its fibres passing horizontally are inserted into the anterior surface of the epiglottis; its action tends to keep the position of the epiglottis permanently vertical. 3d. The *ligamentum glosso-epiglottideum* arises from the base of the tongue; it lies in the median mucous folds between the tongue and epiglottis, and is inserted into the anterior surface of the epiglottis immediately above the ligamentum hyo-epiglottideum. Its action is nearly the same as that of the last-named ligament, but it is also connected with the motions of the base of the tongue.

The tracheo-cricoidean articulation. — The lower margin of the cricoid cartilage is articulated with the first ring of the trachea by a series of the same ligamentous fibres which connect the rings of the trachea with each other. At the anterior mesial base of the cricoid there are found additional ligamentous fibres. The elastic tissue which connects the larynx with the trachea permits considerable freedom in the multiplied movements of the neck without impeding the regular transmission of the atmosphere. In these movements the first ring of the trachea passes within the inferior margin of the cricoid cartilage.

The intrinsic articulations of the larynx are, 1st, the crico-thyroid; 2d, the crico-arytenoid. Besides these may be included the articulation of the arytenoid with the cartilages of Santorini. The cuneiform cartilages are generally unarticulated in man.

The crico-thyroid articulation.—The inferior cornua of the thyroid are curved forwards and inwards. Their extremities present oblique planes directed inwards and downwards, which are firmly attached by a capsular ligament to the oblique discs on the sides of the cricoid, directed upwards and outwards.

The ligament of this joint is of an orbicular form, radiating in oblique fasciculi, the posterior fibres of which extend nearly to the crico-arytenoid articulation.

The crico-thyroid ligament. Syn. *Pyramidal, or conoid ligament.* Lat. *Ligamentum crico-thyroideum.* Fr. *Membrane, ou ligament thyro-cricoïdien moyen.* The crico-thyroid ligament is a very thick, strong, yellow elastic ligament, arising from the mesial line of the inferior margin of the thyroid; it then crosses the crico-thyroid space, and is inserted into the superior margin of the cricoid. This ligament supports the anterior part of the cricoid cartilage, and trachea in conjunction with the crico-thyroid muscle. The nature and position of the articulation of the thyroid, with the cricoid, render the force of this ligament of great utility and importance.

The *lateral crico-thyroid ligament, lig. crico-thyroid laterale*, arises immediately at the side of the crico-arytenoid articulation. Some fasciculi, according to Cruveilhier and Lauth, are attached to the bases of the arytenoids, others are reflected horizontally forwards to the inferior margin of the cricoid. It is bounded externally by the thyro-arytenoideus and crico-arytenoideus lateralis, and lined internally by the mucous membrane of the larynx.

The crico-arytenoid articulation.—The oblique articulating convex surface of the cricoid is received in a corresponding channel or groove at the base of the arytenoid cartilage. The ligament arises from the cricoid, and radiates both anteriorly and posteriorly round the base of the arytenoid cartilage; a fasciculus is reflected along the base of its anterior membrane behind the attachment of the thyro-arytenoid ligament. The crico-arytenoid ligament is thick and strong, yet sufficiently loose to permit a diversity of motion. Some anatomists divide the ligament into anterior and posterior. The articulation is lined and lubricated by a synovial membrane.

The thyro-arytenoid ligaments. Syn. *Chordæ vocales*, Ferrein. *Stimmbänder*, Germ. These ligaments, as their name implies, connect the thyroid with the arytenoid cartilages, and are instrumental in the production of voice. There are on each side two vocal cords, a superior and an inferior; the cavities between these ligaments are termed the ventricles of the larynx. The inferior thyro-arytenoid ligaments, or, as they are often denominated, "the true ligaments of the glottis," are much thicker and stronger than the superior: they present the form of nearly rectangular parallelograms, and are stretched horizontally across the long axis of the larynx, from the anterior horizontal tubercle of the arytenoids, to the angle formed by the junction of the wings of the thyroid (*c, fig.* 27). On their outer side these ligaments are connected with the thyro-arytenoid muscles; their anterior extremities are inserted into the thyroid, the posterior to the arytenoid cartilages; the internal margins are free to vibrate. On exposing them by the removal of the mucous membrane they are found less than their apparent volume. Immediately after death they are semi-transparent, very elastic, and composed of parallel fibres. They are connected with, and form a continuation of the ligamentum crico-thyroideum lateralis (*k, fig.* 24). The length of the vocal ligaments varies with the general dimensions of the larynx: in the adult male they are much longer than in the female. In infancy they are very short, and increase from that period to the age of puberty in an arithmetical ratio. Thus, if at one year old their length in parts of an inch is 0,2500, at five years they will be 0,3333, at nine 0,4166, and at fourteen 0,4999: these are close approximations.

The superior thyro-arytenoid ligaments or superior vocal cords are, in contra-distinction to the inferior, denominated (though incorrectly) the false ligaments: they are of less thickness and strength than the inferior ligaments, and are further removed from the axis of the larynx (*l, fig.* 24). They arise from the internal angle of the thyroid, and are inserted into the middle of the anterior superior prominence of the arytenoid cartilages (*fig.* 24); they are composed of a few slender fasciculi of elastic fibres, approaching less nearly the mesial plane than the inferior ligaments; they appear more prominent, in consequence of their forming the roof of the ventricles. They are in the same plane as the aryteno-epiglottic muscle, and are connected with the fibres of the lateral crico-thyroid ligaments.

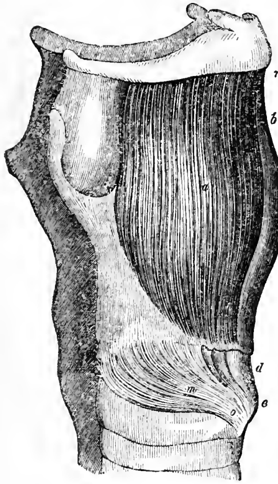
According to M. Lauth there is a connexion between the crico-thyroid, the lateral crico-thyroid, and thyro-arytenoid ligaments by three fasciculi, one of which is vertical, one horizontal, and one ascending (*g, k, n, fig.* 24), the first of these being the crico-thyroid; the second the lateral; the third connects the thyro-arytenoid with the superior thyro-arytenoid ligaments, and lines the bottom of the ventricles. M. Lauth considers also that the thyro-epiglottic, the hyo-epiglottic, and glosso-epiglottic ligaments are composed of the same elastic tissue. Müller and Cruveilhier concur in these views. They certainly appear of the same colour and texture under the microscope, and undergo the same change by exposure to the atmosphere: they also possess the same cohesive elastic properties. The strength of the inferior thyro-arytenoid ligaments is so great that they will tear away the cartilage to which they are attached without being injured, and will support the force of many pounds weight.

Muscles.—The motions of the larynx are exceedingly complex, and are performed by two sets of muscles, which are divided into two classes:—1, the extrinsic; and, 2, the intrinsic muscles. The muscles which elevate the larynx are the digastrici, stylo-hyoidei, mylo-hyoidei, genio-hyoidei, and hyo-glossi, and those pharyngeal muscles which are inserted into the cricoid and thyroid cartilages. The muscles which antagonize these and lower the larynx are the sterno-hyoidei, the omo-hyoidei, the sterno-thyroidei, and the thyro-hyoidei. The os hyoides is the centre of motion for the action of these muscles. (See Neck, Muscles of the.) We shall here confine our description to the

Intrinsic muscles of the larynx, Syn.; *muscles intrinsiques*, Cruveilhier.—The muscles of this division comprise those acting exclusively on the larynx itself. There are four pairs and one single: 1, the *crico-thyroidei;* 2, the *crico-arytenoidei postici;* 3, *crico-arytenoidei laterales;* 4, *thyro-arytenoidei;* and, 5, *arytenoideus*, which, from a difference in the direction of certain of its fibres, is divided into the oblique and transverse. Independently of these, there are some muscular fasciculi, named the *thyro-epiglottidei* and the *aryteno-epiglottidei*.

The *crico-thyroidei.*—These are very short, thick, almost quadrangular-shaped muscles, situated on each side of the anterior part of the larynx: they arise from the anterior and inferior surface of the cricoid cartilage, on each side of the median line. The fibres are fleshy: the most internal directed obliquely upwards and outwards (*m*, *fig.* 25), the central very

Fig. 25.



A side view of the larynx with the os hyoides attached.

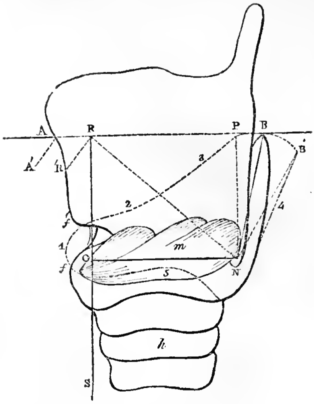
a, the thyro-hyoideus muscle; *b*, the middle thyro-hyoid ligament; *e*, the pomum; *d*, the crico-thyroid ligament; *m*, the crico-thyroid muscle; O N, the direction of the inferior fibres of the crico-thyroid lying nearly perpendicular to the axis of the crico-thyroid articulation; *f*, the trachea; *n n*, the insertion of the thyro-hyoid muscle and membrane to the inner margin of the os hyoides.

obliquely, and the inferior almost horizontally to the inferior margin of the thyroid and to the inferior horn: others are inserted into the posterior surface of the thyroid. A portion of this muscle is prolonged to the inferior constrictor of the pharynx.

Each crico-thyroid muscle is covered by the sterno-thyroideus, and lies external to the crico-arytenoid lateralis and the thyro-arytenoideus. The triangular space between the crico-thyroidei is occupied by the crico-thyroid membrane.

The action of the crico-thyroidei is to rotate the cricoid on the thyroid. The superior and middle fibres are at the greatest distance from the axis of rotation (N, *fig.* 26), and consequently acting as if at the arm of a long lever. In this action the anterior superior margin of the cricoid is elevated towards the inferior edge of the thyroid from *f* to *f′* (*fig.* 26), by which the posterior upper margin of the cricoid is carried backwards from B to B′ indicated by the dotted line 1, 2, 3, 4, 5, (*fig.* 26), and as the space is greater from A B′ than A B, it is manifest that the space in the mesial plane

Fig. 26.



A view of the left side of the larynx to illustrate the functions of the thyro-arytenoid, the sterno-thyroid, and crico-thyroid muscles.

The dotted line 1, 2, 3, 4, 5, shows the position of the cricoid cartilage when the crico-thyroid muscles have closed the crico-thyroid space; *m*, the crico-thyroid muscle; N, the crico-thyroid articulating axis; A B and B A, the directions of the force of the thyro-arytenoideus muscle; R S, the direction of the force of the sterno-thyroideus muscle meeting that of the thyro-arytenoideus in R; R N, the resultant of the combined muscular forces R P and R S; O N and P N are perpendicular lines drawn from the directions of the forces of the thyro-arytenoideus and sterno-thyroideus muscles to the common axis of rotation; they are also the cosines of the angles R N O, R N P, and B N P, and show the amount of force on the axis of the sterno-thyroideus and thyro-arytenoideus muscles respectively; R′ and A′ are the points which R and A must pass through when the thyroid is rotated forwards on the cricoid; A, the point opposite which the thyro-arytenoideus is inserted into the posterior angle of the thyroid cartilage; B, the point on which the thyro-arytenoid acts in rotating B towards A; *f f′*, the crico-thyroid space; *h*, the trachea.

must be enlarged to an amount equal to the difference of the distance A B and A B′ (*fig.* 26). The action of this muscle, therefore, is to stretch the thyro-arytenoid ligaments. The direction of the force of the inferior horizontal fibres of the crico-thyroid which are lying parallel to the line O N (*fig.* 25 and 26) being nearly perpendicular to the axis of rotation, can have, consequently, little or no effect, until the superior fibres have (by raising the cricoid) produced an angle with the axis N (*fig.* 25); they assist only when the crico-thyroid space is diminished. It has been commonly supposed that it is the thyroid which is drawn forwards on the cricoid, and Cruveilhier adopts this supposition; but it has been refuted by Magendie, and not only do we observe that the attachments of the crico-thyroidei are mechanically directed to produce a rotatory motion of the cricoid, but the latter has no fixed point of

The line G C is the vertical projection of the crico-arytenoid articulating axis; *c c*, *f*, *g*, *h*, represent the same parts as in *fig.* 27.

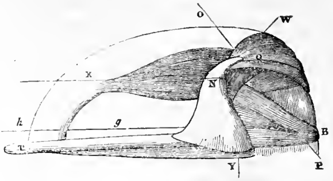
attachment or muscles appropriated to fix it as a fulcrum for motions in an opposite sense.

The *crico-arytenoideus lateralis* is an irregular quadrilateral muscle, arising from the superior margin of the cricoid, from thence passing upwards and backwards, (*f*, *fig.* 28). It is inserted into the posterior surface of the external prominence of the arytenoid cartilage by a tendon common to it and the thyro-arytenoid muscle. It is deeply seated under cover of the thyroid cartilage and crico-thyroid muscle. The action of this muscle has caused much diversity of opinion. Cowper, Haller, Magendie, and others consider that it opens the glottis; but Bichât and Söemmering that it closes it. Its action has, however, been mechanically solved in the following manner by Willis. The arytenoid cartilage is loosely fixed to the cricoid by ligaments already described at B (*figs.* 28 and 29). The direction of the force of this muscle is represented by the line N X (*fig.* 30), having its point of insertion into the cricoid about X. The fibres in passing thence to the arytenoid (*f*, *fig.* 28) lie nearly parallel to the projection of the axis of motion, G C; the tension of this muscle in the direction N X (*figs.* 29 and 30) tends to bring N X B into the same straight line and approximate the point V to the mesial plane; and as N is above the line joining B X, it will depress N and still more V, because the cartilage turns on the articulating surface beneath Q. The action, therefore, of this muscle is to approximate the anterior arytenoid prominences and depress them.

The *arytenoideus* (obliquus and transversus). Modern anatomists consider this as one muscle, but owing to the obliquity of the fibres of one of its fasciculi with respect to the other, some have made a division of it into arytenoideus obliquus and a transversus. It is a very short thick muscle, occupying the concavities on the posterior surface of the arytenoid cartilages and the interval between them. It consists of two layers; the superficial layer, which is composed of the oblique fibres, which arise from the base of the right arytenoid, and crossing the fibres of the deep-seated layer, are inserted into the summit of the left arytenoid cartilage: this is the *arytenoideus obliquus* of Albinus. The deep-seated layer is thicker and stronger than the superficial; its fibres, which are directed transversely from one arytenoid to the other, constitute the arytenoideus transversus of Albinus. The arytenoid muscle is covered posteriorly with mucous membrane, which is connected to it by loose cellular substance, in which some mucous follicles are found; anteriorly it corresponds with the posterior surfaces of the arytenoid cartilages, and is connected by some muscular fibres and membrane with the superior margin of the cricoid cartilage and with the whole length of the internal margins of the arytenoid cartilages. The immediate effect of the contraction of the arytenoid muscles is to approximate the posterior internal surfaces of the arytenoid cartilages, but their action, at the same time, tends to separate the anterior prominences, and to open the chink of the glottis. To counteract this effect the action of the crico-arytenoideus lateralis is called simultaneously into play, and the joint effect of these two muscular forces, represented by the lines N X and NY (*fig.* 30,) produce a resultant in the direction of W N; hence the crico-arytenoideus lateralis and the arytenoideus muscle acting together tend to close the glottis posteriorly.

The thyro-arytenoideus.—This is one of the most important, most complicated, and perhaps least understood of any of the muscles of the larynx. It arises from the side of the angle of the thyroid cartilage, occupying about two-thirds of its height, and reaches within two or three lines of its superior margin. The central fibres are directed horizontally backwards and outwards, slightly inclined upwards, and inserted into the prominence and concavity on the lateral surface of the arytenoid (*l*, *fig.* 27). The superior fibres terminate in the external ridge of the arytenoid; some of them pass round the arytenoid, and enclose the arytenoid muscle like a sphincter.* The inferior fibres which arise near the median plane (*k*, 29) are inserted, at a greater distance from it, into the arytenoid cartilages (*f*, *fig.* 30); some external fibres are directed more eccentrically

Fig. 30.



A portion of fig. 29 *enlarged to demonstrate the direction and result of the forces of the muscles of the larynx.*

O P, the horizontal projection of the axis of articulation; T V, the vocal ligament; *g h*, the direction of the force of the thyro-arytenoideus; N X, of the crico-arytenoideus lateralis; N W, of the crico-arytenoideus posticus; N Y, of the arytenoideus transversus.

upwards and backward, corresponding to the superior ligaments and ventricles, where, according to Lauth, they terminate without reaching the arytenoid. Some fibres of the thyro-arytenoid take an oblique direction backwards and downwards, arising immediately below the superior internal margin of the angle of the thyroid, and are inserted into the vertical prominence of the arytenoid cartilage; they are sometimes detached from those passing horizontally, as in *d*, (*fig* 28,) constituting the thyro-arytenoidei superiores of Albinus, but they are sometimes described as one muscle.

The thyro-arytenoideus corresponds to the internal surface of the thyroid cartilage, from which it is separated by some loose cellular and adipose tissue. Internally it is in contact with the inferior vocal ligament, which lies in contact with the thickest part of this muscle, the bulk of which causes the vocal ligaments on each side to project towards the mesial line and contracts the aperture of the larynx. Some anatomists consider that the thyro-arytenoid ligaments consist of nothing more than the tendons of these muscles; it is not difficult, however, to prove the contrary by dissection.

The functions of the thyro-arytenoidei, concerning which there has been much diversity of opinion, produce several changes in the relative position of the internal mechanism of the larynx, and therefore they require rigid investigation. The effects of these muscles may be considered, first, with respect to the tension of the vocal ligaments; secondly, to the aperture of the glottis. We observe that the points of attachment (at *d d' l*, *fig.* 27) of the thyro-arytenoid are situated within those at A B, (*fig.* 28); and, as the arytenoid cartilage is tied by ligamentous fibres to the point B, it follows that the contraction of this muscle will draw upon the point B, through the interposed arytenoid cartilage: if A be made the fixed point, the contraction of this muscle will draw the point B towards A by rotating the cricoid on the thyroid. If, on the contrary, B be fixed, then A will approach B by the rotation of the thyroid on the cricoid. In both these cases the distance from A to B is diminished, and as the vocal ligaments are situated in a direct line

Fig. 29.

The mucous membrane is removed to shew the ligaments and muscles of the glottis. N F, N F, the arytenoid cartilages; T V, the vocal ligaments; N X, the right crico-arytenoideus lateralis, the left is removed; X *v* L, the ring of the cricoid capable of rotating on the axis R S; *e e*, the crico-arytenoidei postici; E, the junction of the wings of the thyroid.

* Lauth, Mem. de l'Acad. de Méd. 1835.

passing through A and B, this muscle must consequently relax them.

The closing of the anterior and central portion of the glottis by these muscles, or that part lying between T and V (*fig.* 29), is effected, according to Mr. Willis, partly by the approach of the point V of the arytenoids towards T arising from the obliquity of the axis of rotation, and partly by the swelling of the muscle whilst contracting to approximate the arytenoid cartilages tending to fill the space T N X V (*fig.* 29), and to close tightly the sides of the passage below the vocal ligaments; thus closing the anterior and central portions of the glottis.

The question as to how A is made a fixed point, in the above demonstration, remains to be solved. Mr. Willis remarks that while all writers agree that the crico-thyroidei serve to approximate the cricoid cartilage to the thyroid, either by raising the cricoid or by depressing the thyroid, none of them have shown how the cartilages are to be separated again. Let us investigate this proposition. In order that the motions necessary to dilate the crico-thyroid space be effected by muscular motion, it is obvious that A must be made a fixed point, so that B′ may be drawn to B (*fig.* 26), by which *f*″ ascends to *f*, the object in question (*fig.* 26). It is clear that the crico-thyroid muscle cannot be employed in this instance, as it has been already shewn that its action is to force B to B′ and *f* to *f*″; whereas we have now to reverse the direction, and to bring back B′ to B, so that *f*″ may descend to *f*. The sterno-thyroidei are the only muscles, which by their origin, insertion, and direction of force are calculated to effect this purpose; the insertion of one of these muscles being about the point R at an angle with the axis R N (*fig.* 26), its force in the line R O S (*fig.* 26) cutting the right line O N at O; the effect of which will be to draw forwards and downwards the thyroid cartilage from A to A′, and the point R R′; these muscles have the advantage of acting on the extremities of a lever equal to the line O N. When any force equal to that in R S is acting simultaneously with that of the thyro-arytenoideus, in the direction A R P B perpendicular to R S, the composition of these forces R S and A R P B will produce a resultant in the diagonal R N, which will cut the axis N; and as by hypothesis the forces R O and R P are equals, R and consequently A will be fixed points; but the attachment of the thyro-arytenoid at B makes an angle with the axis in the line B N, and the perpendicular cutting the direction of the force of this muscle produced to the axis is P N; thus whilst the sterno-thyroid has, by its action on the lever O N, fixed the points A and R, the thyro-arytenoid may act with an equal force at the point B on the lever P N; but as the force P N is produced on the cricoid (which is free to move by the relaxing of the crico-thyroid), the result will be to rotate the point B towards A, and depress the point *f*″ to *f*, and thus the question is solved. In the preceding demonstration it must be remembered that the point R is assumed to be that in which the whole of the sterno-thyroid is inserted, whereas it is expanded upon the surface around the oblique ridge, but any of its fibres below R will have the same effect as if at R, provided they are in the line O S. It must also be borne in mind that the thyro-hyoid prolongs the action of the sterno-thyroid to the os hyoides; but in this instance the os hyoides itself descends simultaneously with the expansion of the crico-thyroid space, and we know that the sterno-thyroid is always in action during the descent of the larynx. There is, however, very little muscular force required for rotating the cricoid in the direction in question. It is therefore evident that the sterno-thyroid is the antagonist to the thyro-arytenoid, and that, in this instance, during the rotation of the cricoid on the thyroid in the direction B B P A must be the antagonist to the crico-thyroid.

From the preceding demonstrations we conclude that when the crico-thyroidei, the thyro-arytenoidei, the crico-arytenoidei laterales, and the arytenoid muscles are acting simultaneously, the chink of the glottis is entirely closed. Another function of the thyro-arytenoidei relates to their effects during the production of vocal sounds, which will be considered in the article Voice. In order that the glottis may be closed in the manner just described, it is necessary that the crico-thyroid assisted by the sterno-thyroid should have fixed the fulcrum for the play of these muscular motions.

The crico-arytenoidei postici.—The intrinsic muscles of the larynx already described tend, more or less, to affect the antero-posterior diameter of the laryx, the tension of the thyro-arytenoid ligaments, or the contraction of the chink of the glottis. The crico-arytenoidei postici have altogether a different tendency. They are a pair of muscles arising at the posterior surface of the cricoid (*e e*, *figs.* 27 & 28); the superior and middle fibres ascend obliquely, the inferior nearly vertically to be inserted into the lateral prominences at the bases of the arytenoid cartilages, anterior to the crico-arytenoidei laterales.

These muscles lie under the mucous membrane of the pharynx, and upon the posterior surface of the cricoid.

The contraction of these muscles is generally said to draw the arytenoids backwards, outwards, and downwards, and to open the glottis posteriorly. This view is in a great degree, but not strictly, accurate. The crico-arytenoideus posticus being inserted into the arytenoid cartilage at N has the effect of acting as on the arm of a short lever at N, and of rotating it upon the axis O P, in the direction of N W, which is directly opposed to the direction of the force of the crico-arytenoideus lateralis, which is represented by W N, therefore the effect of this muscle is to separate the vocal ligaments, and consequently to open the chink of the glottis. Mr. Willis remarks that the thyro-arytenoidei postici do not draw the arytenoids backwards, as described by anatomists, which implies that the posterior fasciculi of the ligamentous fibres of the crico-arytenoid articulation at B (*fig.* 30) are relaxed; for, although some fibres lying nearest the mesial plane are directed to draw the arytenoids towards B, they are counteracted by the fibres lying furthest from it, and by assuming the whole to act together, the resultant will be as nearly as possible perpendicular to the axis of articulation O P, which would open the glottis; and therefore he concludes that the force of the thyro-arytenoidei postici in a direction backwards may be neglected. Bichat erroneously considered that they assist the thyro-arytenoidei and crico-arytenoidei in drawing the thyro-arytenoid ligaments very tense.*

The thyro-epiglottidei.—These are a pair of small muscles situated between the anterior surface of the thyroid cartilage and epiglottis; they arise from the internal surface of the thyroid near its middle, and not far from the origin of the thyro-arytenoidei; their fibres are directed upwards and forwards to the base of the epiglottis, to which they are inserted behind the ligamenta thyro-epiglottidea.

Their action is to depress the epiglottis.

The aryteno-epiglottidei are two small muscles, arising from the superior pyramid of the arytenoid cartilages posterior to the arytenoid muscles, or from the fibrous raphé situated vertically behind them; they pass upwards and forwards to the sides of the epiglottis, and upon the posterior border of the thyro-epiglottic membrane.

Action.—Owing to the direction of their fibres, the thyro- and aryteno-epiglottidei tend to depress the epiglottis, or rather to effect the tension of the aryteno-epiglottic mucous folds.

The action of the intrinsic muscles of the larynx may be briefly recapitulated as follows:

The crico-arytenoidei postici open the glottis; all the other muscles close it.

The arytenoideus obliquus and arytenoideus transversus approximate the arytenoid cartilages posteriorly. The crico-arytenoidei laterales and the thyro-arytenoidei bring them in contact anteriorly. The thyro-arytenoidei close the centre of the glottis, and with the crico-thyroidei, assisted by the sterno-thyroidei, regulate the tension, position, and vibrating length of the chordæ vocales.

The crico-thyroidei and sterno-thyroidei antagonise the thyro-arytenoidei, and in stretching the crico-thyroid ligament, the sterno-thyroidei with the thyro-arytenoidei antagonise the crico-thyroidei.

The crico-arytenoidei laterales, and thyro-arytenoidei, and the arytenoideus obliquus and transversus antagonise the crico-arytenoidei postici. These last-named muscles likewise may be said to antagonize all the muscles which close the glottis.

The genio-glossi, the linguales, the stylo-pharyngei, and crico-pharyngei, and hyo-glossi, are muscles associated in common with the motions of the tongue, pharynx, and larynx, and belong rather to the structure and functions of the two former of these organs than to the larynx, and consequently are considered only as auxiliary.

The motions of the internal mechanism of the larynx being effected by muscles, whose forces are directed, with respect to each other, in various degrees of obliquity, and in different planes, and producing by their combination results which can only be demonstrated on mechanical principles, it has been deemed desirable to introduce them into the preceding investigations to insure greater precision of detail and accuracy of result, and the more especially as we find in the works of our best anatomical writers the most discordant opinions, based apparently upon mere hypothesis or superfical observation, and without reference to any data or principle from whence their conclusions are drawn.

The perusal of the works of Albinus,* Haller,† Cowper,‡ Söemmering,§ Meckel,|| Bichât,¶ Magendie,** and Bell,†† confirm these remarks; exceptions to these observations are found in the works of Borelli,‡‡ Barthez,§§ E. and W. Weber,|||| Bernouilli,¶¶ Barclay,*** and Willis;††† from the invaluable investigations of the latter much assistance has been derived.

Bloodvessels.—The arteries of the larynx are derived from the superior thyroid, a branch of the external carotid and from the inferior thyroid, a branch of the subclavian. Small veins accompany the arteries and empty themselves into the neighbouring trunks.

Structures called glands.—The arytenoid gland. Syn. *Glandulæ arytenoideæ*, Morgagni, Bichat, Cloquet; *cartilago cuneiformis*, Wrisberg, Bandt. The arytenoid gland is an inappropriate designation given to the cuneiform cartilage by Morgagni,‡‡‡ whose views of the structure of this body are adopted by Bichât,§§§ Cloquet,|||||| and Cru-

veilhier.* The description given of it by Morgagni is, that it consists of a granular substance of a livid whitish colour, from which under the pressure of the epiglottic or neighbouring muscles a fluid is poured out. Wrisberg† described it as a cartilage under the name of cuneiform. Cuvier and Wolff, as before stated, have confounded it with the cartilage of Santorini. Morgagni appears to have mistaken for glandular the yellow elastic tissue penetrating its body. Lauth describes some mucous follicles about its base and internal surface, but he opposes the views of Morgagni on the constitution of this body. This body is sometimes absent in the human subject, but scarcely ever in the quadrumana. Its structure is decidedly cartilaginous.

The epiglottic gland. — Syn. *glandula epiglottidis*, Fab. Cass. Morg. The epiglottic gland is a name given to a mass of yellow ligamentous adipose and cellular substance, situated in the triangular space between the anterior surface of the epiglottis and the angle of the thyroid cartilage; it is bounded anteriorly by the thyro-hyoid membrane, above by the thyro-epiglottic mucous membrane and ligament; below, by the union of the epiglottis with the thyroid cartilage, and on each side by the mucous membrane passing from the thyroid to the epiglottis. Berengarius speaks of it as a fleshy gland: Steno and many others as composed of granules, whose ducts perforate the epiglottis and open on its posterior surface. Fabricius, Casserius, and Morgagni ‡ have described and figured these supposed granules and ducts. Bichât,§ Cloquet,|| Quain,¶ and most modern anatomists adopt the same views. Morgagni, upon the same supposition as he had formed of the nature of the elastic tissue, considers the composition of the epiglottis to be chiefly glandular. Cloquet and Bichât admit the difficulty of detecting any follicular structure, nor could we discover any under the microscope; and from what has been already stated on the structure of the epiglottis, we conclude, as of the arytenoid, that the structure which enjoys the name of epiglottic gland is not glandular.

Mucous membrane.—The mucous membrane of the larynx is continuous with that which covers the mouth and pharynx. The posterior surface of the larynx is bounded by the pharynx, and is lined by mucous membrane both on its anterior and posterior surfaces. If the statement of Cruveilhier be correct, this singular duplication is not to be found elsewhere in the animal economy; afterwards it is reflected over the surface of the base of the tongue, and lines the interior surface of the epiglottis; in this space it forms three folds, called *glosso-epiglottic*, often described as the middle, and two lateral, which adhere closely to the surface of the epiglottis. The mucous membrane being reflected over the free part of the epiglottis, to which it rather closely adheres, then lines its posterior surface and dips into the larynx.

A duplication called the *aryteno-epiglottic* fold passes from each side of the lateral margin of the epiglottis to the vertical apophysis of the arytenoid cartilage. This membrane is connected posteriorly with the mucous coat of the pharynx, and lines the posterior surface of the larynx; it is reflected over the arytenoid cartilages, and with the aryteno-epiglottic fold forms the posterior and lateral superior margin of the larynx; covers the superior thyro-arytenoid ligaments, penetrates to the bottom of the ventricles; from thence, after lining the inferior thyro-arytenoid ligaments, it passes through the chink of the glottis, covers the thyro and crico-arytenoideus lateralis muscles, and the internal surface of the cricoid cartilages, and becomes the investing membrane of the trachea.

The laryngeal membrane is perforated by numerous mucous orifices of a peculiar pale rose-colour, and is remarkable for its great sensibility, more especially in the region above the rima glottidis.

The rima glottidis. Syn. *cavum seu sinus laryngis* The chink of the larynx is an aperture directed horizontally, connecting the supra and infra-laryngeal regions, and allowing the free transmission of air in respiration. It is bounded posteriorly by the arytenoid cartilages, arytenoid muscle and mucous membrane; laterally by the arytenoid cartilages and the thyro-arytenoid ligaments, which, with the mucous membrane reflected over them, present nearly rectangular-shaped valves, attached on three sides, leaving one, bounding the glottis, free; anteriorly by the angle of the thyroid. Immediately above it are the ventricles, one on each side. The intrinsic muscles of the larynx not only contribute to its functions in the production of voice, but determine its form. The form of the chink of the glottis is variable; in the state of repose, or that of ordinary respiration, it is triangular, the aperture dilating during inspiration and contracting during expiration. When the arytenoids are separated to the greatest extent by the crico-arytenoidei postici, it assumes a lozenge form; if the posterior bases of the arytenoids are closed by the arytenoid muscles it becomes an ellipse; if the anterior apophyses of the arytenoids meet by the action of the crico-arytenoidei laterales, the chink may be divided into two parts. The length of the chink of the glottis is very variable, and bears a relation to that of the thyro-arytenoid ligaments; like the latter, it increases with age in an arithmetical proportion until the period of puberty; at that time its length in the male sex under-

§ "Cet espace est occupé par un corps manifestement celluleux, et graisseux, dans sa plus grande partie, mais qui est inferieurement recouvré de petits grains glanduleux, tantôt agglommérés, tantôt isolés, lesquels envoient sensiblement des prolongemens dans les trous dont est percée l'epiglotte : les prolongemens paroissent s'ouvrir sur sa surface laryngée, aux orifices qu'on y distingue. Quelquefois les petits corps glanduleux sont tellement masqués par cette graisse jaunâtre, qu'on ne peut les distinguer." Traité d'Anat. descript. tom. ii. p. 385.

|| Anat. descript. p. 245.

¶ Elem. of Anat. p. 858.

goes a sudden development, whilst in the female it remains stationary. The comparative length of the chink in the male and female is proportional to the relative lengths of the vocal ligaments already detailed. The length of the rima glottidis bears no relation to the stature of the individual. In the adult male it is about eleven lines, of which the boundaries formed by the arytenoid cartilages are four, and the thyro-arytenoid ligaments seven lines. In the male and female it is on a mean average as three in the former to two in the latter. In a female, M. Lauth however found the rima glottidis to measure from ten to eleven lines, whilst that of a tall male extended only from eight to nine lines; but this is a rare instance.

The pomum Adami on the thyroid has a corresponding concavity within, which affords a greater length in the mesial section of the larynx, and which tends to increase the longitudinal dimensions of the glottis. In several of the ruminantia the concavity is very conspicuous.* The breadth of the glottis is much less than its length. In a state of repose its transverse section is not more in the adult than about two or three lines, or with respect to its length as two to eleven, but the diameter varies with the intensity of the forces of the intrinsic muscles of the larynx.

The ventricles. Ventricule ou sinus du larynx. Cruv.— These are oval or elliptical cavities directed from before backwards, between the superior and inferior ligaments. The depths of the ventricles are effected by the distance from the free margin of the vocal ligaments to the internal surface of the thyroid, or rather to the thyro-arytenoid muscles, which constitute the bottom of the ventricles. The internal part of the posterior cavity of the ventricles is enlarged and deepened by a duplicature of the mucous membrane passing external to the arytenoid cartilage, which has been described by Morgagni, and recently more particularly by Mr. Hilton† under the name *sacculus laryngis.* The ventricles are prolonged anteriorly, extending along the vocal cords on each side of the epiglottis. In size the ventricles vary with the general dimensions of the larynx; they are each divided into an interior and posterior cavity by a transverse ridge. The ventricles afford greater freedom of motion to the inferior thyro-arytenoid ligaments.

Nerves.—The larynx is exquisitely sensible, and, as we have seen, combines complex and delicate motions with secreting surfaces. These properties result from its nervous endowment, which is derived from two branches of the pneumo-gastric nerve, namely, the *superior* and the *inferior laryngeal nerves.*

It will be unnecessary to enter into any detailed description of these nerves here. Their distribution will be found fully described in the article Par vagum, to which we refer. Let it suffice to mention, that the superior laryngeal nerve by its external branch gives filaments, 1, to the inferior constrictor of the pharynx; 2, to the thyro-hyoid muscle and membrane; 3, to the laryngeal plexus; 4, to the crico-thyroid muscle; 5, to the thyroid gland. The internal branch of the superior laryngeal nerve supplies filaments, 1, to the epiglottis; 2, to the adipose and mucous membrane; 3, to the arytenoid muscles; 4, to the thyro-arytenoideus; 5, to the crico-arytenoideus lateralis; 6, a descending anastomotic branch to the

† Guy's Hosp. Reports, No. v.

recurrent; and, 7, to the aryteno-epiglottic mucous folds and muscles.

The inferior laryngeal or recurrent nerve gives filaments, 1, to the pneumo-gastric and cardiac plexus; 2, to the pharynx; 3, to the trachea; 4, to the œsophagus; 5, to the crico-arytenoideus posticus; 6, to the arytenoideus obliquus and transversus; 7, to the crico-arytenoideus lateralis and thyro-arytenoideus; 8, an anastomosing branch to the superior laryngeal.

Our knowledge of the anatomical distribution of the laryngeal nerves, and of the functions of the intrinsic muscles of the larynx, are sufficient, independently of experiment, to demonstrate the inaccuracy of the well known assertion of M. Magendie, supported by Cloquet, Pinel, Percy, and several others, that the recurrent nerve presides over those actions which *open* the glottis, whilst the superior laryngeal influences those muscles which *close* the glottis. The principal facts opposed to this theory of M. Magendie may be briefly stated as follows. 1. It was well known long before the promulgation of Magendie's views that the inferior laryngeal nerve gave to the arytenoid muscle a filament which had been described by Andersch,* Bichat,† and Meckel,‡ and subsequently by Schlemm Bischoff, Swan, Cruveilhier, Dr. Reid, and others, therefore it has been sufficiently demonstrated that the recurrent nerve supplies the muscles that close, as well as those which open the glottis. 2. M. Magendie has stated that the crico-arytenoideus lateralis and thyro-arytenoideus opened the glottis, whereas in the preceding details it has been proved that these muscles close it. 3. The loss of voice which follows the section of the recurrent nerves results from the paralysis of all the muscles (except the crico-thyroid) which both open and close the glottis, a fact proved by the experiments of Le Gallois and Dr. Reid. The limited space allotted to this article will only permit us to notice the conclusions to which recent experimenters have arrived respecting the functions of the laryngeal nerves. The external branch of the superior laryngeal is composed chiefly of motor fibres, and it controls the action of the crico-thyroid and the other muscles to which it gives filaments. The internal branch of the superior laryngeal is composed of sensitive fibres, which confer the most exquisite sensibility on the mucous membrane of the larynx, more especially in its supra-glottideal region. It is therefore the sensitive and the excitor nerve of the larynx. The inferior laryngeal supplies the muscles that both open and close the glottis, and is chiefly a nerve of motion when it reaches the larynx, but a few of its fibres go to the mucous membrane. The union of the superior with the inferior laryngeal branch by an anastomosing filament, preserves a reciprocal play in the functions of these nerves: whilst the branches anastomosing with the sympathetic, connect the larynx with the ganglionic system; the pulmonary and cardiac branches connect it with the respiratory and circulating systems, and thus associate the larynx with those vital functions. The laryngeal nerves also belonging to the reflex system, impressions made on the sensitive filaments of the larynx are reflected to the medulla oblongata, and propagated by a circuitous route to the motor filaments of the recurrent, so that a long interval is traversed in circulating an impression from the sensitive to the motor nerves of the larynx; but according to the estimate made of the speed with which an impulse is propagated along a nerve, which is assumed to be equal to that of electricity, the time occupied to transmit an impression from the filaments of sensation to those of motion must be inappreciable to our senses. Other important physiological considerations result from recent experimental researches, those of Le Gallois and Dr. Reid in particular. 1. With respect to the motions of the glottis during respiration, the dilatation during inspiration, and contraction during expiration, are the effects of the play of muscular force in opposition to the direction of the current of air in its passage to and from the lungs, the tendency of which is to produce the reverse action.* There is a constant periodical oscillatory motion of the arytenoid cartilages, revolving upon the axis of articulation, O P, (*fig.* 30,) at every expiration and inspiration; hence the necessity of a synovial membrane to lubricate the crico-arytenoid articulation. 2. When the recurrent nerves are diseased, compressed, or cut, so as to paralyse the crico-arytenoideus posticus, the power of muscular action in opposition to the direction of the inspired air is lost. The valves of the glottis are drawn downwards with the air, the anterior apophysis of the arytenoid cartilages rotated inwards, the chink closes, symptoms of suffocation supervene, and asphyxia results.

When spasmodic closure of the chink of the glottis occurs, the obstacle to the ingress of air is increased by convulsive attempts to draw in the breath, which causes a rarefaction of the air below the glottis, and augments the atmospheric pressure above it; and the chest thus, says Dr. Ley, " becomes hermetically sealed." If the aperture of the glottis be partially open, the air rushing through it causes a stridulous sound (*laryngismus stridulus*), whilst in another position of the glottis the crowing inspiration is produced; this effect arises (according to Dr. Ley) from the chink of the glottis being partially open for the admission of air, and remaining so until an explosive expiration such as screaming, coughing, or belching, mechanically bursts open the floodgates, and terminates the paroxysm.

* Fragmentum descr. nervor.
† Traité d'Anat. tom. iii. p. 216.
‡ Man. d'Anat. tom. iii. p. 66.

* In the production of these periodical movements, the action of the muscles is involuntary, but in their action for the purposes of voice, they become subordinate to the will, and therefore belong also to the voluntary system.

Asphyxia is often delayed by the posterior chink of the glottis being retained partially open, in consequence of the coincident paralysed force of the arytenoid muscles, and by the great inclination of the crico-arytenoid articulating axis, with respect to its vertical section, preventing the approximation of the arytenoid cartilages by which the posterior part only of the chink can be closed. When any irritation is produced on the exquisitely sensitive mucous membrane of the larynx, it transmits a reflex action to the motor filaments of the recurrent, and the glottis is spasmodically closed, without any such morbid condition of the recurrent nerve as Dr. Ley supposed necessary.

The larynx, when dissected out, and cleared of its extrinsic structures, presents on its anterior aspect the free margin of the epiglottis, the notch of the thyroid, the pomum Adami, its mesial line, the crico-thyroid space, and ligament, and the anterior border of the cricoid cartilage.

On each side of the larynx are observable a portion of the wings of the thyroid, the crico-thyroid muscle, the great and lesser cornu, the superior and inferior tubercles, the oblique ridge, the superior and inferior margins of the thyroid, the side of the cricoid, with a portion of the lateral crico-thyroid ligament, and the superior, inferior, and posterior margins of the cricoid.

On the posterior aspect are observable, the posterior free surface of the epiglottis, the arytenoid cartilages and muscles, the aryteno-epiglottic mucous folds, the crico-arytenoidei postici muscles, the vertical ridge of the cricoid, the posterior margins of the thyroid, and the posterior surface of the cricoid cartilages.

In the internal surface, from above, we observe the superior margin of the thyroid cartilage and great cornua, forming the superior boundary of the larynx, the superior margin and notch of the epiglottis, the cornicula laryngis, the arytenoid and cuneiform cartilages, the aryteno-epiglottic mucous folds, the superior and inferior vocal ligaments, the ventricles, the rima glottidis, and the mucous membrane.

Looking from below upwards, we perceive the inferior circular margin of the cricoid, the membrane lining its internal surface, the inferior aspect of the thyro-arytenoid ligaments, and the rima glottidis.

The preceding outline of the general anatomy of the larynx will give the reader an idea of its manifold structures, its exquisite sensibility, its complex motions, its connection with the process of deglutition, and its admirable adaptation for the production of sound, and may serve to impress a conviction that it is one of the most elaborate and perfect specimens of mechanism in the human body.*

LARYNX. (Morbid anatomy and pathology.)—The importance of this organ to life, and even when existence is not actually endangered, to the comfort and well-being of the individual, must render any deviation from its healthy and normal condition in the highest degree interesting to the pathologist: nor will that interest be diminished by reflecting on the paramount value of a knowledge of these deviations to every practical physician. Small in size and composed of few and apparently simple structures—its functions so obvious that any imperfection in their performance could be quickly perceived and readily understood—it would appear only reasonable to suppose that its various pathological conditions should have been observed, and the symptoms connected with them long since collected and arranged. Yet, such is not the history of the pathology of the larynx: on the contrary, it presents itself to us with all the interest of a new discovery, and whatever is known on the subject is the result of investigations made within the last few years. We have the opinion of the late Dr. Cheyne, (no mean authority on the subject,) that in the year 1800, "perhaps there was not in Britain more than one individual, namely Monro, who was acquainted with the true nature of the disease of which General Washington died—acute laryngitis;" and the same writer goes on to shew that in ten years subsequent to that general's death, Dr. Baillie, then at the head of the medical profession in England, admitted that he was ignorant of the nature of the same malady. But without reverting so far back, I may be permitted to state, that within a comparatively recent period I can personally remember the lack of knowledge that obtained amongst medical practitioners in this particular, and the deplorable results that too frequently ensued: and although it may be gratifying to reflect on the altered condition of things at present, yet it must be obvious that a subject so short a time under investigation cannot be expected to have been thoroughly worked out. Much as has been brought forward—perhaps more remains behind, and any person now attempting to give an exact and adequate description of the pathology of this organ, may probably find it necessary to bespeak a very considerable degree of indulgence.

Accustomed to consider laryngeal disease practically, and more particularly with reference to operation, I find it difficult to bind myself down to mere pathological arrangement, or to attempt a satisfactory classification. True, like other organs, the larynx is composed of different structures, in each of which disease will assume the character peculiar to itself, and exhibit the appropriate appearances in an examination after death, but it rarely happens that morbid actions are so limited in extent, as to exist and produce their proper results in one tissue without the participation more or less of the others. This will produce confusion, and render it a matter of difficulty to connect symptoms with the existing pathological conditions that occasion them, and may be adduced as an objection to any attempt at arrangement founded upon structure alone: yet there really can be no classification altogether exempt from the same or a similar observation, and therefore I shall adopt this one as having the merit of the greatest simplicity. Following this view then, I find the larynx to be composed of the following structures, viz.:—

1. Mucous membrane, exhibiting all the varieties of inflammation that are observed in that tissue when situated in other organs. Thus inflammation here may be acute or chronic, phlegmonous or erysipelatous, idiopathic or symptomatic, and attended by fever of a typhoid or an inflammatory type. And these varieties producing different effects or results. Thus we have examples of acute idiopathic inflammation with fever of a sthenic kind in the croup of children, producing the adventitious membrane, and in the laryngitis of adults, that terminates so frequently in œdema; and of the same local disease with asthenic fever in the diphtherite and in erysipelas: whilst accident furnishes numerous instances of the results of symptomatic inflammation in the consequences of burns, scalds, penetrating wounds, and the swallowing of caustic poisons. As happens so constantly in other structures, chronic inflammation is here best known by the changes it induces, and furnishes us with abundant specimens of hypertrophy or thickening of the membrane, and of the different forms of ulceration.

2. Submucous tissue, which is the seat of œdematous effusions, and of the sloughy and putrid matter produced by diffuse inflammation.

3. Cartilage, in which we remark great and important varieties of disease, such as inflammation, ulceration, mortification, degeneration into an earthy unorganized material, atrophy, hypertrophy, and some alterations of shape and structure probably depending on scrofula or other constitutional taint.

4. Muscle, the seat of those spasmodic actions so frequent and so perilous in laryngeal affections, and perhaps occasionally of gout and rheumatism also.

5. Ligaments. I know not whether disease ever originates in these structures, but there can be no doubt that they are sometimes removed by ulceration, and there is reason to believe that great inconvenience and even danger may be occasioned by a preternatural relaxation of some of them.

1. Acute inflammation of the mucous membrane is always in the first instance attended by a change of colour more or less intense according to its situation, being comparatively pale where it is closely attached to a subjacent cartilage, but of a deep and concentrated red tint, verging on purple, where it is more loosely connected by the intervention of cellular tissue or muscle. The membrane is also swollen, soft and pulpy, these characters being likewise influenced by the nature of its connection to subjacent parts, and I believe the usual symptom of inflammation, "pain," is not absent, although the mental agony attendant on obstructed respiration renders this a secondary consideration to the patient: certainly in the laryngitis of the adult, pressure on the pomum Adami is very sensibly felt. In connexion with these changes the functions of the organ are interrupted and impaired. The usual secretion of the membrane is diminished in quantity, or perhaps ceases altogether, and hence the sensation of dryness or huskiness in the throat, and the peculiar solitary ringing cough that uniformly is present. The voice is also injured, being occasionally nearly if not altogether lost, and there is difficulty of breathing accompanied by a harsh stridulous sound; this latter being caused by the mechanical obstruction to the passage of air produced either by tumefaction or by spasm. Having continued a given time,—and the first stage of inflammation of the larynx if very acute is usually but short,—certain results or effects are developed, which, differing in the child and the adult, require a brief separate notice for each.

The acute laryngitis of the child, or croup, although generally commencing in the larynx alone, and sometimes altogether confined to it, is by no means uniformly so: on the contrary, it not only may commence in or extend to the trachea, but possibly have its origin in the bronchial cells, and pass thence upwards along the tubes. It may also perhaps not be strictly correct to arrange croup amongst the diseases that are preceded or accompanied by inflammatory fever, for occasionally it makes its attack without any previous warning whatever, and a child that had retired in apparently perfect health may arouse and alarm its attendants in the middle of the night with the sounds of that dry, harsh, and incessant cough, and that loud and stridulous respiration which afford to the practised ear the painful but unerring evidence of the nature of the mischief present. In either case, however, the disease hastens to its second pathological state, in which the evidences of increased vascularity begin to disappear, and are succeeded by the secretion or effusion of a viscid tenacious lymph, which, assuming the form of a membrane, has obtained the name of the false or adventitious membrane of croup. This substance is of a pale yellow colour, viscid and tenacious; more generally found in the larynx than the trachea; seldom occupying the entire circumference of the tube; unorganized; incapable of becoming the medium of union between opposing surfaces, and with a strong disposition to separate from the surface on which it was originally formed. It usually commences in the larynx, and travels downwards along the trachea; more rarely it seems to begin in the ramifications of the bronchial cells; and again, still more seldom is the entire of the mucous membrane attacked at once, and the adventitious membrane thrown out over its whole extent. Considered as a pathological production, this false membrane of croup presents some curious and interesting subjects for observation, for although so generally met with that by some it has been regarded as the essential characteristic of the disease, yet perhaps it is not invariably or necessarily so; at least I have seen cases so far resembling croup in all their stages, that they could not be distinguished from it during life, in which dissection subsequently shewed the mucous membrane swollen, and soft, and pulpy, with copious submucous effusion, yet without the formation of a single flake of lymph. Possibly in the few cases of this description that came under my observation, the disease had proceeded with a rapidity which proved fatal before the membrane had time to have been formed. Again, it is the only* instance of lymph being produced on a mucous surface as the result of active acute inflammation. In chronic affections membranous layers of lymph are often formed, and in different situations, as in the bronchial cells and the mucous coat of the intestines, but the acute produces it alone in the structures that are the seat of croup. And lastly, it appears that this effect of inflammation is restricted to patients under twelve years of age. Mr. Ryland, in his excellent treatise on the larynx, has published a table from Bricheteau, by which it is shewn from the experience of fourteen distinguished authors, that croup "has never occurred at a later age than twelve years, and very rarely at that age." My friend, Dr. W. Stokes, considers the cases published as examples of croup occurring in the adult as not being inflammatory croup at all, but analogous to the diphtherite of Bretonneau, which will be shewn to be a very different disease indeed.

Such is the pathological condition of the parts in the second stage of croup—a condition indicated by the increased difficulty of breathing—the pale and swollen countenance—the straining eye—the dilated nostril and the purple lip; by the occasional expectoration of some portions of the false membrane; and (as happens in every affection of the larynx) by severe and protracted spasms of the glottis. If the patient still continues unrelieved, the third and last stage supervenes. The child still breathes with difficulty, but with increasing languor: its countenance is pale; its lip bloodless; there are generally convulsions, in one of which the fatal event may take place; or else he sinks gradually, exhausted and worn out, and dies comatose. And we are to look for the actual and immediate cause of death not to the larynx but to the lungs and brain. No matter how much the membrane may be swollen, or how extensively the false membrane may have been formed, the rima is not completely closed, and the patient dies, not because there is an absolute insufficiency of air to provide for the arterialization of the blood, but because some change has taken place in the organ by which this most important function is performed. When the thorax is opened the lung does not collapse under the influence of atmospheric pressure: when the lung is cut into, it is found to be loaded with dark blood and with frothy serum, the effusion of which latter is often so abundant as nearly to fill the trachea. The brain, if examined, is found congested, and not unfrequently is there an effusion of serous fluid into its ventricles.

The acute inflammation of the mucous membrane of the larynx bears no resemblance in the adult to that in the child, excepting only in the agonizing difficulty of respiration and the fatality of the result, but the pathological conditions are different, and therefore is the disease in the adult far more manageable. I can scarcely conceive, much less describe the existence of acute laryngitis to any dangerous extent in the membrane alone without the participation of the submucous tissue, in which the perilous tumefaction is generally, if not always, seated; I shall, therefore, as I have hitherto done, consider this affection in connection with its principal pathological result—the formation of an œdematous effusion.

Mucous membranes in every situation seem to be connected to the adjacent tissues by that species of cellular membrane termed reticular, as a provision that the courses of the canals of which they form so important a part should not be impeded by any accumulation of fat: and this reticular membrane is more or less lax according to the nature and consistence of the subjacent structure. Where mucous membrane is attached to bone, the nature of the connecting medium is so short and close, that in many instances it is scarcely observable, and the membrane, in addition to its own functions, appears to perform that of a periosteum, whilst in other situations, as in the intestine, it is so lax as to allow the organ to become distended to an almost unlimited extent. The usual effect of inflammation on this reticular tissue is an effusion of a serous fluid within its cells, and the production of œdema; but this is of little consequence where the tissue is dense and close, and perhaps of still less where the organ is widely distensible. The larynx, however, presents an organ of a mixed character—the mucous membrane is here attached to muscle and to ligament, and these

* For an apparent exception to this rule, see a case published in the Dub. Journ. of Med. Science, September 1838, No. 40, vol. 14.

again are supported and restrained by resisting cartilages externally, so that if the submucous tissue which is here so loose as to allow the membrane to be thrown into natural folds, should become the seat of infiltration, the swelling so produced cannot take a direction outwards, but must tend to compress and close the aperture of the glottis. This is the œdema of the glottis, a formidable and too often a fatal affection, but nevertheless presenting very considerable pathological varieties. Thus it is sometimes attended by fever, and forms only part of a more extended inflammation, involving tonsils and fauces, pharynx and larynx: again, it is purely local, confined to the larynx alone, and so entirely free from any accompanying fever, that the patient only complains of the difficulty of breathing and the cough. It is often idiopathic, but may be produced by injury, and is a common result of swallowing caustic poisons and boiling water; nor is it in this latter respect confined to the adult, for I have thus seen the superior aperture of the glottis, in a very young child, pursed up and closed as if by the drawing of a running string. It may be situated only in a part of the larynx, the rest remaining free; thus it is no uncommon occurrence to see only one side of the glottis puffed and swollen, and the slit-like aperture thus converted into a curve; but the most interesting because the most practical illustrations of partial œdema will be found in cases published by Sir Henry Marsh, in which the disease appeared to be confined to the epiglottis alone.* Lastly, I believe it is possible to have this œdema produced without any external evidence of inflammation. In the Museum of the School of Park-street there is a preparation shewing it as apparently occasioned by the vicinity of a large carcinomatous tumour.

Considering the pathology of this affection, the degrees of inconvenience and of danger likely to result from it will be easily understood. The symptoms will be, a loss or imperfection of voice, which is generally very well marked, the utmost effort at articulation amounting to no more than an indistinct whisper; and difficulty of respiration, including cough and other signs of local irritation. The danger will probably be in proportion to the rapidity with which the effusion is formed, for life may be maintained with a wonderfully diminished supply of air to the lungs, provided the diminution takes place gradually and slowly: but it may not arise solely from this cause, for here, as in every other form of laryngeal disease, spasmodic exacerbations are painfully frequent, and place the patient's life in momentary danger. Dissection, therefore, developes three different causes of death. One, the most infrequent where the patient has perished by spasm: the glottis, although swollen, is still pervious—perhaps apparently sufficiently so for the ordinary purposes of respiration; but in order to observe the relaxation after spasm, several hours must be allowed to elapse between death and the post-mortem examination, for the bodies of those who die of laryngeal disease become extremely rigid, and remain in this state a considerable time. A second, in which the effusion having been poured out with great rapidity, the rima is found mechanically blocked up, and immediate suffocation occasioned: in this case neither the lungs nor brain are engaged, at least not necessarily. The third is, where the disease has lasted three or four days or more, the œdema has been developed but slowly, and the diminution of the supply of air been less sudden: in these cases, besides the symptoms of strangulation, others, indicative of a congested condition of the lung and brain, are observed during the latter periods of existence, and corresponding morbid appearances are discoverable after death.

Very severe inflammatory affections of the mucous membrane of the larynx are unfortunately too frequent to admit of doubt or to create difficulty; but a good deal of confusion has arisen from an attempt to identify them, or some of them, with croup, because an exudation takes place from the surface in some respects resembling the adventitious membrane formed in the latter disease. One of these has been described with graphic accuracy by M. Bretonneau of Tours, by him supposed to be the same with croup, and named Diphtherite: but although the differences between these affections have been observed and pointed out, the name is still frequently applied (I fear) without very precise ideas attached to it. The exact disease described by Bretonneau I do not profess to have ever seen, neither have I heard of it, unless in one instance in a family in this country which lost four of its young and interesting members by a visitation at least bearing some resemblance to it. In hospital I have heard the name applied to some throats which I never should have thought of identifying with that described by the French writer, and I feel satisfied that the attempt to mix up different and it may be opposite diseases under one generic name has done anything but simplify the study of pathology. If, however, by asthenic croup or diphtherite is meant the peculiar local disease which accompanies the eruption of scarlatina anginosa, or which is frequently met with without any cutaneous eruption, especially in adults—which is accompanied throughout by low and typhoid fever, and is often propagable by contagion—then is the affection well known and its description easy: but it bears no similitude whatever to inflammatory croup. For besides that the constitutional affections are totally opposite, a circumstance of the greatest importance as influencing the progress of the respective cases, the local symptoms and appearances have marked and distinct characters. Thus the asthenic angina is always ushered in by shivering and other precursors of fever; the soreness of the throat is intense from the very commence-

* See Dub. Journ. of Med. Science, March 1838, v. 13, no. 37. This excellent paper of Sir H. Marsh's contains many illustrations of the same fact.

ment, and the part is even painful on pressure externally; every attempt to swallow is so dreadfully distressing that patients will suffer to be half-famished rather than attempt to get down a spoonful of fluid. In attempting to examine the throat there is often great difficulty, because the patient either cannot, or from the pain it occasions, will not open his mouth; but if it can be seen, it is observed to be of a deep red colour, verging on purple, sometimes diffused over the surface, sometimes in patches, and even from an early period abundantly covered by a thick glairy tenacious mucus that it is difficult to wipe from it. If the disease is severe, the membrane soon becomes sloughy: " the colour of the slough is grey or ashey: in some few instances it appears brown; its edges are abrupt and well defined, and it is surrounded by inflammation of an intensely deep red colour. The slough is in general slow in separating, and when thrown off it appears to resemble a membrane of viscid lymph not unlike the adventitious substance formed in croup, and the surface underneath looks of a bright red colour, is nearly level with the adjoining parts of the membrane, and seems more like the blush of erythema than the relic of mortification. I believe that wherever croup has appeared to have been contagious it will be found that malignant scarlatina has prevailed also; and that the occurrence of the laryngeal or tracheal disease was occasioned by the spreading of the inflammation from the fauces to the windpipe, or perhaps by the actual presence of one of these sloughing ulcers in the immediate neighbourhood of the glottis."*

Such is the description of the effects of angina maligna on the mucous membrane written in the year 1825, but without any suspicion on the part of the writer that it could ever be ranged by the side of the affection termed croup: for besides the essentially opposite characters of the fever in each, which by themselves would be all-sufficient, there are the following differences. The angina maligna, diphtherite, or by what other appellation it is to be known,—for with respect to it we enjoy a most happy abundance of nomenclature,—commences always in the fauces, and when it attacks the windpipe, which is by no means very frequent, it does so secondarily by spreading to it; whereas croup seldom or never commences in the fauces unless when it appears as the sequela of some serious injury, such as the swallowing of boiling water. Cynanche maligna even locally is not confined to the mucous membrane, as is evidenced by the intense pain in swallowing, the difficulty of opening the mouth, the enlargement, suppuration, and even gangrene of some of the adjacent glands; and it occasionally exhibits something like a metastatic transfer of disease to some important organ, such as the brain or liver. And even when recovery takes place, the difference is still remarkable: it is slow, often imperfect, and followed by anasarca or some similar evidence of a broken and cachectic habit. This is not the place to enter more fully into the examination of these two diseases, which the reader will find admirably contrasted in Dr. W. Stokes' work on diseases of the chest, where the angina is spoken of under the name of secondary croup.

There remain two other affections of the larynx to be noticed accompanied by asthenic fever, in both of which the pathological condition of the submucous tissue is of great importance, viz. erysipelas and diffuse inflammation. I believe the larynx is very seldom the primary or original seat of an erysipelatous attack, at least such has not come under my observation; but I have not infrequently seen it seized either by the spreading of the disease from the head and face, or by some species of metastasis. The constitutional symptoms during life are of a low and typhoid character; the local, those of painful and difficult deglutition and respiration, and the termination (as far as I know) always fatal. Nor are the appearances after death always satisfactory, for, as in other cases of erysipelas, the tumefaction often subsides and the colour fades very soon after death. In most instances, however, we find the mucous membrane of a pale yellow colour and apparently greatly thickened: the submucous tissue filled sometimes with serum, sometimes with a gelatinous lymph, and sometimes with a sloughy and putrid matter; the natural folds of the organ obliterated, and the rima more or less blocked up and closed by the thickening and tumefaction of the adjacent parts.

But one of the most curious affections to which the larynx is liable is that of diffuse inflammation. I say " curious," because it is not necessary that the mucous membrane should be inflamed or thickened or otherwise engaged, or that there should be any remarkable swelling of the parts, and yet the breathing is harsh, sibilous, or croupy, as if from the presence of some mechanical obstruction. In these cases, which are always fatal, the cellular tissue is the seat of the disease, and is found filled with offensive purulent matter and flakes of unorganized lymph, sometimes around the larynx, trachea, and œsophagus, sometimes at the front of the throat, and not infrequently extending to a considerable distance down into the anterior mediastinum.

Chronic inflammation of the mucous membrane of the larynx resembles in its effects a similar form of disease in other structures, except that as the aperture of the glottis is small, and its functions essential to life, the same degree of alteration or of disorganization cannot have place here that may occur in other situations without the patient generally experiencing a degree of distress that will at least direct his attention to the subject. Still is this affection sufficiently insidious, and its progress in many instances so slow, that often irremediable mischief is produced before assistance is sought for: and thus it happens that we are obliged to speak of chronic inflammation, not with re-

* Potter on the larynx and trachea, p. 17.

ference to its commencement or the early periods of its progress, but to its effects or products, which, exhibiting various forms of derangement and disorganization, shew to the morbid anatomist the length of time the work of destruction must have been in operation, and the extraordinary changes of shape and form and structure that may occasionally be endured consistently with the maintenance of a miserable existence.

The simplest form of altered structure in the mucous membrane that I am aware of is that effected by a slow but progressive deposit (probably of lymph) within its substance, which renders it firmer, thicker, and more solid; and although this must occasion inconvenience and difficulty of respiration to a certain extent, and is troublesome from the dry cough and occasional spasmodic exacerbations that accompany it, yet perhaps, whilst restricted to this stage, it is seldom perilous to life. But these alterations of structure, particularly if neglected, are seldom quiescent, and however slow in their progress have a tendency to move forward either to a morbid or perhaps malignant change of the tissues, or to the partial removal of these by the process of ulceration. Thus, ulcers of the larynx, however heretofore overlooked by pathologists, are now found to be extremely common, and I know of nothing more difficult than to subject the numerous varieties of them to any form of classification. They cannot be arranged according to structure, for they are very seldom so superficial or so insulated as to engage the mucous membrane alone; neither can they be classed according to the symptoms they occasion, for the suffering of the patient or even his ultimate danger does not seem entirely to depend on their extent or character. The most practically useful division of these ulcers would be as to their exciting cause if it could always be discovered; yet even here there is so much uncertainty of symptom during life and such diversity of appearance after death as to render the subject obscure and unsatisfactory.

In some instances the larynx becomes the seat of idiopathic ulceration, that is, the disease seems to have been occasioned by cold or other causes of local irritation—at least such is the only explanation to be offered. "Thus the laryngeal surface of the epiglottis and the internal parts of the organ itself may be studded over with numerous minute aphthous ulcerations; sometimes the edges are marked by a yellow line of superficial excoriation, bordered by a deep blush of inflammation; and in these cases I have always observed, during life, that great pain and difficulty of deglutition accompanied the symptoms of dyspnœa, and often formed the most prominent feature of the case. Occasionally the ulceration is deep and foul, and spreads with an almost phagedenic destructiveness: these sporadic sores, usually commencing above, either in the soft palate or the back of the pharynx and spreading downwards, too often involve the destruction of the patient. Occurring as they constantly do in bad and cachectic habits, they are little under the control of medicine, and operation, however it may prolong existence, scarcely holds out a hope of ultimate recovery."

In other cases the ulceration seems to be sympathetic, and either precedes or follows certain affections of the lung. Thus in cases of tubercular consumption, aphonia is often a very distressing symptom, sometimes accompanied by difficult respiration, and occasionally by painful deglutition. In these instances not only is the larynx studded over with specks of ulceration, but the trachea and bronchial tubes leading to the cavity in the lung present a similar appearance, as if the matter possessed some corrosive quality and its passage over the mucous membrane became the cause of its ulceration. These appearances have been too frequently observed not to have attracted the notice of the morbid anatomist, but still it is extremely difficult to connect them with disease of the lung in the relation of cause and effect, for sometimes the loss or imperfection of voice precedes or at least is amongst the earliest symptoms of consumption, and in other instances it only becomes manifest in the very latest stages. It is easy to conceive that the presence of an ulcer in the larynx, by producing difficult breathing and occasioning a diminution of the supply of air, may determine the development of an abscess in a scrofulous lung already well disposed to such disease; but when the ulceration has occurred at a late period, and the difficulty of swallowing, the aphonia, and stridulous breathing appear among the closing symptoms of consumption, it will be difficult to account for the appearances observed, unless by supposing them to be sympathetically produced.

But of all the causes from which ulcerations of the larynx are known to proceed, some specific or constitutional taint seems to be the most influential, such as syphilis, scrofula, mercury, or a combination of two or more of these. As far as my own observation extends, I cannot say I have ever seen the larynx engaged in a case of venereal where no mercury had been used, but on the other hand there is scarcely any organ more likely to be attacked where the medicine has been imperfectly or improperly used, or in which the attack is more perilous and unmanageable. Sometimes the larynx becomes ulcerated in consequence of phagedena or other destructive form of the disease spreading downwards from the throat or fauces, but more frequently is it engaged alone. The ulcers here are seldom solitary, but present several spots of ulceration, and in some cases are so extensive that the whole configuration of the organ is spoiled and lost, the epiglottis being partially or entirely removed, and the chordæ vocales and ventricles carried away. The surface of this extensive ulceration is irregular, warty, and gives the appearance of uneven granulation, and there are chaps and fissures that pass deeply into the substance of the subjacent cartilage, portions of which are removed. When the ulcers are more superficial they very often exhibit the herpetic appearance and the tendency to spread observed in mercurial sores, healing in one situation whilst fresh ones break out in the neighbourhood, and cicatrizing with a depressed surface and evident loss of substance. With respect to symptoms, the loss or imperfection of voice will very much depend on the situation of the ulcers; but the difficulty of breathing and general distress are by no means criteria by which the extent of destruction of parts can be estimated, for sometimes there is uncommon suffering where the ulceration is extremely limited. Very frequently these ulcers (particularly if the epiglottis is engaged) produce symptoms of difficult deglutition, exactly resembling those of stricture of the œsophagus: but this is only during the time the sores are actually open, for, when healed, swallowing is performed with astonishing facility, even although the greater part of the epiglottis may have been carried away.

But the most interesting fact in connexion with these ulcers is, that by rest and proper treatment they are susceptible of cure, and fortunate it is that by means of operation we are enabled to afford this important organ the requisite degree of repose. Mr. Carmichael has published two most interesting cases illustrative of this fact; in which the patients recovered, and in which we have consequently a right to infer that the ulcerations healed. In the summer of 1838 I operated on a woman in the Meath Hospital, who had symptoms of such extensive destruction of parts as must have proved fatal, but who nevertheless recovered with a complete capability of breathing through the rima, but with nearly a total loss of voice. The healing of this kind of ulceration may be inferred from that case also, but it is proved by the following observation: "In the Museum of the School of Park-street, Dublin, is a preparation taken from a poor woman who had been an inmate of the Meath Hospital ten or eleven different times for venereal ulceration of the larynx, and finally died there quite suddenly, as if from the effects of spasm. It shews where a large portion of the epiglottis had been removed, the ulcer having healed by a puckered cicatrix. From below the left ventricle a longitudinal scar extended a full inch and a half down into the trachea, the contraction of which had diminished the calibre of that part of the tube very sensibly The right ventricle was totally obliterated, and on different spots about the superior part of the trachea there were several small pale depressed cicatrices, evidently the results of former sores that had been open at different periods at which she had been in the hospital. The only ulcer that existed at the time of her death was a very small one, with ragged irregular edges, situated midway between the natural position of the right ventricle and the root of the epiglottis."

The softer tissues of the larynx are also occasionally liable to gangrene, circumscribed—confined to the organ itself and not exhibiting any tendency to spread. Of this I have as yet seen but one example, and that one under circumstances that rendered it doubtful whether the disease should not be considered as sympathetic with a similar affection of the lung. It was the case of a man who died in hospital of gangrene of the lung supervening on acute pneumonia. Seven days before his death he was attacked with symptoms of laryngeal disease, hoarseness, with difficult and laborious breathing, which gradually increased until the voice was nearly lost and respiration quite stridulous. After death, besides the gangrene of the lung, a gangrenous ulcer was found, involving the chordæ vocales at the left side: its surface was about the size of a shilling, and of a dirty green colour; its edges quite sloughy, and its centre excavated to a considerable depth: the mucous membrane around highly vascular and covered with a pellicle of lymph.

3. The cartilages of the larynx are subject to very important diseases, some of which seem to be peculiar to fibro-cartilage in this particular situation, and all of which are attended with inconvenience and danger by reason of their interfering with the function of the organ. I shall commence with that which I believe to be the most frequent, the most important, and the most fatal; indeed, when allowed to run its own course it is always destructive, and when the patient's life is preserved by art, it is with the alternative of breathing for ever afterwards through an artificial aperture. In consequence of the similarity of symptoms between this and phthisis pulmonalis, it has obtained the name of phthisis laryngea.

The exact manner in which this disease commences and the causes that lead to its production have not yet been so accurately ascertained as to admit of no farther doubt or question; for instance, Mr. Ryland seems to think that "in most instances it is secondary to some inflammatory affection of the laryngeal mucous membrane or its subjacent tisssue," whereas I have ventured to believe that the original morbid action was set up in the cartilage itself and was proper and peculiar to it; at the same time it must be confessed that I have seen it apparently produced by the presence of an abscess in the immediate vicinity, and I believe there can be no doubt of its being an occasional sequela of typhus fever. The essence of the disease seems to be a change of structure in some of the cartilages, followed by the death and disorganization of the newly formed material, and an attempt at its removal by abscess and ulceration. Thus on a post-mortem examination of one of these cases an abscess is always found in the situation of some of the cartilages—very generally of the broad posterior part of the cricoid: and this abscess has burst by one or more openings, one of them being very frequently just behind and above the rima. On cutting into the cavity of the abscess, besides the matter, which is greenish, putrid, and abominably fetid, particles of a grey or white earthy material are found, and there are always portions of bone, thin, ragged at the edges, white and perfectly dead. When the disease has so far progressed, there is always other and more extensive mischief; the exterior parts in the neighbourood are swelled and thickened, the mucous membrane ulcerated; the arytenoid cartilages often detached; and the epiglottis, in every case that I have seen, more or less removed by ulceration. The whole configuration of the organ is lost or spoiled, and scarcely bears a resemblance to the natural shape and appearance of a healthy larynx. We cannot even form a conjecture of the causes that occasion this formidable disease, or of the circumstances that dispose to its production. At some time beyond the middle period of life the cartilages of the larynx, except the epiglottis, and often of the trachea also, become converted into bone, and from the circumstance of carious bone being so constantly found in these abscesses, it would appear that it is either during the process of ossification or immediately afterwards that the disease commences. I have always imagined that it was at the former of these periods, and that the affection was produced by some imperfection or irregularity in, or deviation from, the ordinary and natural process—in a word, that this earthy unorganized material was formed instead of healthy bone. I had once an opportunity of seeing a case which I regarded as an example of the commencement of this disease, in the person of a man who, having suffered from laryngeal symptoms for some months, suddenly died in the Meath Hospital, apparently from the effects of spasm. "On slitting up the larynx, the cricoid cartilage appeared to be highly vascular and organised. Its substance was internally as red as blood, and in three or four places there were specks of an earthy white substance that crackled under the knife, and was evidently of the same nature with that usually found in caries of the laryngeal cartilages." I am aware that one case can prove but little, particularly in pathological science, but opportunities of seeing the incipient stages of such an affection as this must be very rare, and every case ought to be recorded that will in any manner tend to throw light on a disease the etiology of which is so extremely obscure.

However occasioned, this earthy degeneration of the laryngeal cartilages is an extremely insidious disease, its approach being so gradual as scarcely to alarm the patient, and its progress slow. There is usually sore throat and difficulty of swallowing, although this latter is not necessarily a constant symptom; hoarseness, and at first but triflingly impeded respiration. These inconveniences in the commencement are not such as to produce much distress; for I have known one patient suffer for three months and another nearly nine, before either applied for relief, and in both the disease had a fatal termination. Afterwards, however, the symptoms become much more aggravated, the difficulty of breathing is exceedingly distressing, and there are exacerbations that bring the patient to the point of death by suffocation. I have already noticed one case in which dissolution took place at a very early period, and when the occurrence could only be explained by the suddenness and severity of the spasm. At length, as the dyspnœa becomes extreme, the patient suddenly experiences some partial relief; his cough, which was before teasing and troublesome, now becomes softer, and the expectoration free and copious. This latter has all the characters of purulent matter, and there are, mixed with it, particles of that white, gritty, earthy substance already described. Occasionally, pieces of the size of a pea of this unorganised substance are coughed up, and when they appear they leave very little doubt of the nature of the complaint. Towards the latter end of the disease the breathing becomes loud and sonorous, with a whistling noise, so as to be heard at a considerable distance. The cough is incessant; the expectoration copious, with a peculiarly fetid gangrenous smell; the patient's breath has this odour also, which may also be regarded as an unfavourable symptom. There is at all times convulsive struggling for breath, with occasional exacerbations. In most cases, but not in all, the chest becomes affected; there is pain in some one part of it or other, with a sensation of tightness round the thorax as if the patient could not draw a full inspiration. His strength seems to give way rapidly under these symptoms; his body becomes emaciated; he has night sweats accompanied with excessive restlessness; and at last he sinks exhausted in the struggle and dies.

Throughout the entire progress of the disease there is seldom any well-marked paroxysm of fever, although the pulse is never much under 100; however, this may be attributed to the constant irritation under which the patient labours. The tongue is usually clean; the appetite good—in some instances ravenous; and the general functions of the body, with the exception of respiration, seem to suffer but little. The countenance is always pale, with that sickly dirty hue that characterises hectic fever. The expression evinces great anxiety; and this is so remarkable that patients suffering under this species of cynanche often seem to bear a strong resemblance to each other.

It is now familiarly known to surgeons that even this dreadful condition is not utterly divested of hope, and patients in whom this disease had wrought such ravages as to render the larynx quite unfit for the performance of its functions, nevertheless survived for years after an artificial opening had been practised in the trachea. Some of these patients have since died, and thus in a limited degree afforded opportunity for examining the extent of destruction produced, as well as proving the all-important practical fact, that ulcerations here, however extensive, are capable of being cicatrized if the organ is only left in a state of repose. In the Museum of the Royal College of Surgeons in Ireland is the larynx of a patient who lived for more than two years after having been operated on by Mr. Purdon of Belfast, and the following are the appearances exhibited by the preparation. About half the epiglottis had been carried away, and the edge of the remnant is cicatrized. The space between the root of the epiglottis and the rima, rough on its surface, irregular and warty. The ventricles altered in shape, diminished in size, but not obliterated. The dimensions of the rima greatly diminished. The canal of the larynx is not more than one-third of its natural size, and is lined by a thick uneven membrane, evidently the product of cicatrization, and the place which should have been occupied by the broad portion of the cricoid cartilage exhibits an empty cavity, as if that structure had been removed by absorption or some other process, and nothing deposited in its room. One of the patients on whom I operated in the year 1829 died about a year since in the Fever Hospital, and the larynx was examined by the surgeon of that institution, Mr. Trant; it presented appearances so nearly similar to the above as not to require particular detail, and quite sufficient to shew that the original destruction had been such as totally to preclude the possibility of the organ ever being capable subsequently of performing the ordinary function of respiration.

The cartilages of the larynx are also liable to mortification following on inflammation, and apparently produced by the causes that induce gangrene in other structures. I suppose this affection to be extremely rare, as I have met with but two cases, and have not heard of its being observed by others. In one of these cases a large abscess existed in front of the larynx and upper part of the trachea, in which the thyroid cartilage lay like a foreign substance entirely denuded, mortified, and abominably offensive, its appearance resembling that of wetted rotten leather. The front of the cricoid cartilage and of the two upper rings of the trachea had been removed by mortification also. The lining membrane of the larynx was thickened, corrugated, and had a granular appearance; part of it was ulcerated, through which the abscess had communicated with the pharynx. The remnant of this larynx is preserved in the pathological collection of the School in Park-street, and shews that at least five-eighths of the organ had been totally and entirely destroyed. It proves that such a disease must be utterly hopeless and irremediable, and that, quite independent of the constitutional derangement that must lead to its formation and accompany its progress, no chance could exist of cicatrization and subsequent recovery.

Occasionally, although I should suppose very rarely, the cartilages of the larynx are the subjects of an alteration of structure strongly resembling the ordinary product of scrofula. Of this I have seen but one specimen, for which I am indebted to the kindness of my friend Dr. Benson. December, 1838. A man, æt. 39, was received into the City of Dublin Hospital, under the care of Dr. B. for the treatment of what was considered to be chronic rheumatism. It was soon discovered that the pains were not rheumatic, but most probably depended on cerebral disease. The larynx presented a firm tumour externally, and there was an almost total loss of voice. He died, and after death scrofulous tubercles were discovered in the brain. The larynx was of a healthy structure in every part except in the thyroid cartilage, the alæ of which were converted into a firm scrofulous mass, about the size of a large chesnut on each side. The scrofulous or tubercular matter appeared to have been deposited originally in the centre of each ala. The margins and cornua of the cartilage were unaltered, and the cartilaginous structure seemed to lose itself insensibly on the surface of the tumour.

This very interesting preparation is preserved in the Museum of the Royal College of Surgeons in Ireland.

Besides these deviations from the ordinary healthy conditions of the cartilages of the larynx, it is certain that one at least of them presents appearances of abnormal changes both of size and shape. Morbid thickening or hypertrophy of the epiglottis, as well as its opposite state of contraction or shrivelling, have been spoken of by authors, but I have never been fully satisfied that the former of these was not rather the result of a thickened condition of the mucous membrane than of the cartilage itself, and I believe the latter never is seen unless as the consequence of previous ulceration. A deviation from its usual shape is by no means very uncommon in this cartilage, most instances of which are trivial and unimportant, and are probably congenital; but in some few instances the change is more remarkable. One of these has been noticed by Dr. Stokes in the chapter of his work which treats of diseases of the larynx and trachea, and by him it is termed the leaf-like expansion of the epiglottis. He describes it thus: "This has not been described by any author, but a most remarkable preparation of the disease exists in the Museum of the School of Anatomy and Medicine in Park-street. The epiglottis is thinned and singularly elongated, and its form so altered as to represent the shape of a battledore, the narrow extremity being next the glottis. In the preparation alluded to it is fully two inches in length, and coincides with double perforating ulcers of the ventricles. Nothing is known as to the history of the case, but I have seen more or less of a similar alteration in other cases of laryngeal disease."

In a paper professedly devoted to abnormal anatomy, I know not whether I am warranted in noticing derangements of function, unattended by any lesion of structure discoverable by dissection, yet there are some of these exhibited by the epiglottis which seem deserving of the attention of the physiologist. The use ascribed to this cartilage of protecting the larynx during the process of deglutition is well known, yet observation has furnished us with examples of exceptions to this use, both positively and negatively; for, as when this valvular structure is altogether removed (by experiment in animals and by disease in man), the larynx is nevertheless often found able to protect itself, and the subject to swallow both liquids and solids without much, and occasionally without any inconvenience, so, on the other hand, it is a fact which cannot be controverted, that the epiglottis sometimes seems to be deprived of its protective sensibility, and permits the free introduction into the windpipe of substances attempted to be swallowed. This latter fact I first noticed in the case of a Wapiti deer which was bronchotomized by Sir Philip Crampton: it frequently discharged portions of its food through the wound, and yet after death the larynx in all its parts was found apparently perfect in its organization. But not to rely on observations made on the inferior animal, a case soon afterwards occurred in the Richmond Surgical Hospital, of a young female wounded in the trachea rather low down in the neck. From this wound portions of the ingesta frequently escaped, and yet after death the larynx was found healthy, its organization complete, and no unnatural communication whatever between the œsophagus and windpipe in any part or situation whatever. I have since had a precisely similar case under my care in the Meath Hospital. These are instances in which the epiglottis seems inert, and the larynx is left patulous and unprotected; there are other cases in which it appears to be morbidly active, although it is difficult to explain the agency by which such activity is produced. In prosecuting some experiments on the subject of asphyxia, a stout middle-sized dog was let down into a brewing vat that had been emptied of the fermenting liquor about ten minutes previously; he was to all appearance perfectly dead in two minutes. After allowing the body to remain thus for twenty minutes, it was examined: the glottis was found to be of a very pale colour, and the rima completely shut up by the close approximation of the arytenoid cartilages. *The epiglottis was shut down like a lid upon a box, so as perfectly to close the superior aperture of the larynx*: this latter was a curious appearance, and I know not what muscles could produce the effect, but the fact was witnessed by Dr. Hart, now one of the professors of practical anatomy in the College of Surgeons, by Dr. Young, and others. I am also ignorant as to whether a similar condition of the epiglottis obtains in men who have been suffocated by carbonic acid; human subjects are seldom examined so soon after falling into a state of asphyxia as to allow of the immediate appearances being observed, and yet information on this point would be of great value in determining the suitable means for attempting resuscitation.

The most difficult part of the pathology of the larynx to contend with is that which has reference to muscular organization, and unfortunately it is that which has been least examined, or on which examination has thrown the faintest and most unsatisfactory light. Furnished with an exquisitely delicate and beautiful arrangement of muscle, the normal actions of which are exemplified in the production of the different sounds of the voice, and in giving force to the exit of the air in coughing, sneezing, &c. it would appear only reasonable to suppose that the functional derangements of the larynx should be accompanied by some appreciable corresponding lesion of its muscular apparatus; yet such does not seem to be the case, at least not invariably, and we sometimes find the voice impaired or perhaps lost, the muscles of the organ exhibiting their ordinary appearance, and again remarkable and seemingly important lesions without much injury to voice or respiration. Under these circumstances we must speak of the morbid appearances that have been observed in the first instance, and consider the irregularities of function afterwards.

The muscles of the larynx are sometimes found in a state of extraordinary developement amounting almost to hypertrophy. I know not how far this may be considered to be an abnormal condition, or whether it may not be the natural result of great and constant employment of the organ: reasoning from analogy this latter seems more probable, but dissection has hitherto thrown no light upon the subject.

They are likewise subject to atrophy or wasting, the fibres appearing thin, pale, and attenuated. Andral mentions cases of loss of voice in which he sometimes found the fibres of the thyro-arytenoid muscle wonderfully atrophied, and sometimes separated from each other by some morbid secretion, either of pus or tubercular matter. I have been informed by Sir P. Crampton that he has seen in the Museum of the Veterinary College in London, several preparations illustrative of the disease termed "roaring" in the horse, which seems to be produced by an atrophy of the arytenoid muscles. A relaxation is thus effected which allows to the arytenoid cartilages an unnatural degree of mobility. Whilst the animal is at rest or moving slowly, the current of air passes gently, and there is no "roaring;" but when he is put to greater speed and respiration becomes more hurried or more forced, the little valves are acted on, the rima is proportionably closed, the breathing becomes stridulous, and that peculiar noise so well known to persons conversant with horses is produced.

Lesion of function in the muscles of the larynx exhibits itself in the opposite conditions of atony and spasm. Examples of the former are to be found in some cases of partial paralysis where the patients become totally incapable of uttering any sound, however indistinct and inarticulate; in the hoarseness and sometimes loss of voice that suddenly attacks young persons, particularly females, from exposure to cold and damp; and perhaps frequently in the sympathetic aphonia that precedes or attends on phthisis. On the pathology of these affections morbid anatomy has thrown but little light, nor is it surprising that the subject has attracted a minor degree of attention, when it is recollected that the more severe laryngeal symptom, that of difficult respiration, is seldom or never present. I have had two cases of aphonia attended with pain and soreness in the larynx, which, under an idea that the disease was either gout or rheumatism, I treated with colchicum with apparently favourable results. I know not whether the supposition that the larynx may be the seat of either of these painful affections is correct or not, but I see no reason why it should enjoy so fortunate an exemption. However, although atony of the muscles of the larynx may not be attended with much peril, a spasmodic action of them is always eminently perilous, sometimes destroying life with a rapidity that almost precludes the possibility of assistance. There can, therefore, be few subjects more interesting to the practitioner, and although, as might be expected, the causes that produce these terrific affections have not been explained, yet it may be desirable to examine into the symptoms and some of the circumstances that occasionally precede or accompany them.

Spasm of the glottis is either idiopathic or symptomatic.

The idiopathic occurs, as far as I know, only in children, as in the "spasmodic croup," or laryngismus stridulus, unless we also choose to include within this class the hysteric dyspnœa that occurs in young females.

The symptomatic occurs as indicative of, or in connexion with,

1. The application of some deleterious substance to the larynx, as carbonic acid, boiling-water, or steam.

2. The application of some irritating material, as a particle of salt.

3. The presence of a foreign body within the trachea or bronchial tubes.

4. The presence of a foreign body in the œsophagus.

5. The existence (occasionally) of an aneurism of the aorta.

6. The existence of any other disease within the larynx or trachea. Any of these latter may be present in the adult or the child indifferently.

Few diseases have attracted more attention than the spasmodic croup of children; few have been more accurately described as to symptoms, and in none is our pathological information more deficient; a fact that may almost be proved by the number of different names by which it has been designated. It is the asthma of infants of Millar; the cerebral croup of Pretty; the spasm of the glottis of Marsh; the spasmodic croup of other writers; and the laryngismus stridulus of Mason Good and Ley. It occurs in very young children, with a peculiar difficulty of breathing, attacking for the most part suddenly, accompanied by a crowing sound, and oftentimes with a suspension of respiration for several seconds. This difficulty of respiration varies in intensity from a single crow to a more prolonged paroxysm threatening suffocation, and terminates when in recovery by a long deep-drawn respiration, with a peculiar stridulous noise; when in death, by such convulsive struggles as might lead, and indeed have led, to a belief that the cerebrum was engaged. Pallid and exhausted, the child falls lifeless upon the nurse's arm, and is then generally said to have died in a fit. In these cases there is no cough; no raucal sound of voice; no continued stridulous breathing, except an occasional mucous rattle heard only while the infant sleeps be considered as such; there is no fever; and on examination after death no trace of inflammation, nor indeed any deviation from the ordinary healthy appearance of the organ, can be discovered. Under these circumstances, pathologists had no method of explaining the phenomena but by spasm, an irregular and involuntary contraction of the muscles of the larynx closing up the rima glottidis to a greater or less extent, and in proportion to such closure interfering with and obstructing respiration.

But what is the cause of this spasm? Some have supposed it to have an intimate connexion with an hydrocephalic tendency, because it has been sometimes seen in children with large heads and sluggish dispositions, and because signs of cerebral congestion have been discovered after death; but I have seen the disease prove fatal to the liveliest and apparently most healthy children, and the congestion may just as well be the consequence as the cause of the closure of the glottis. Others again have referred it to the general constitutional irritation that proceeds from painful dentition, and doubtless cases have occurred in which the crowing respiration was relieved by successive scarifications of the gums, according as each tooth became prominent underneath; but this, although teaching an important practical lesson, leaves the pathological connexion between the facts in as much obscurity as ever. According to others there is a constitutional tendency to this disease in some children, a fact which it must be conceded has been painfully exemplified in more families than one; but this hereditary disposition to disease, although abundantly obvious, is too imperfectly understood to be discussed with any thing approaching to pathological accuracy. Lastly, improper or unwholesome food, indifferent clothing, a close and tainted atmosphere, and exposure to vicissitudes of climate, have been regarded as influential exciting causes, and change of circumstances in these respects has often produced an almost magical amendment in the condition of our little patients; but still we are at a loss to discover the immediate modus operandi of these pernicious influences, or why they should be determined to the larynx in the form of an involuntary spastic contraction of its muscles.

Other causes have been assigned for the production of this disease, some of which are eminently deserving of attention; at the same time it may be observed that its being attributed to such a number of influences shews that its real exciting cause is probably still unknown. For instance, either this disease or an affection bearing a strong resemblance to it, has been described by Dr. Kopp, and afterwards by Dr. Hirsch of Königsberg, under the name of thymic asthma, and by them attributed to an hypertrophied condition of the thymus gland, which by its weight and volume presses on the heart, the lungs, the large arterial and venous vessels, and prevents the free exercise of their functions. Dr. Montgomery has published an interesting paper on this subject, in which he attributes the sudden death to an enlargement of this gland, whether that arises from hypertrophy of its substance or an alteration of its structure from scrofula or other disease; and explains how agitation or excitement may suddenly distend and increase the size of the organ in such a manner as to affect materially the condition of the surrounding parts. Again, in the work by Dr. Ley already referred to, a different explanation has been offered. Apparently relying on the experimental researches of Magendie and Le Gallois, he supposes that, if the recurrent nerves are compressed to such an extent as to have their functions impaired, the glottis, under the influence of the superior laryngeal branches, would become and continue fast closed. The cause of the disease then, according to him, will be found in some tumour, scrofulous or otherwise, so situated as to create an injurious degree of compression on the recurrent nerves. That an enlargement of the thymus gland may, from its situation, produce great and serious inconvenience, it would be absurd to question, and perhaps there is sufficient evidence to shew that it may occasion the symptoms and results of this very disease: but it is far from being proved that spasm of the glottis may not occur, and even prove fatal in cases where no such enlargement existed. Alterations of size, shape, and structure, even if rapid, take place gradually, and their results should be gradual also, whereas this disease has been known to destroy its victim in its first and only paroxysm; and moreover, if structural change in the gland was its sole exciting cause, it would be difficult to account for its sudden disappearance on the removal of the child to the country and its diet being changed. Whilst therefore it may not be denied that hypertrophy of the thymus can occasion the phenomena by others attributed to spasm of the glottis, there is not sufficient proof of its being the general or even frequent cause of this peculiar disease. I shall have occasion to notice the supposed consequences of pressure on the recurrent nerves hereafter.

It is questionable how far spasm occasioned by the contact of noxious or irritating substances can justly be termed sympathetic, for they are the results of an application of a direct stimulus: it is immediate in its effects, and more or less complete according to the nature or quality of the exciting cause. Death from total submersion in carbonic acid gas occurs so quickly as almost to seem instantaneous, and the spasm entirely occludes the glottis. The mildest form of spasm seems to be that occasioned by the accidental admission of some particle of food which is usually expelled again very quickly by a cough sufficiently distressing but seldom dangerous: yet instances have been known of the apparently trifling occurrence of the introduction of a particle of salt being attended by a fatal result.

However, when spasm is, or appears to be produced by the presence of a foreign body in the œsophagus or the trachea, or by the pressure of an aneurismal tumour, it is evidently sympathetic, and it may be interesting to inquire into the evidence by which such relation of cause and effect is established.

I had formerly entertained the opinion that spasm of the glottis should be the consequence of some irritation applied to the larynx itself, and not external to or at a distance from it, and therefore that the presence of a foreign body in the œsophagus ought not to hold a place amongst its exciting causes. I have since, however, altered my views on the subject, and indeed, when we consider the number of circumstances under which this morbid action may occur, we cannot be justified in denying it in this case in opposition to most respectable testimony. Mr. Kirby has published a case in the Dublin Hospital Reports, in which death was apparently produced by spasm of the glottis in consequence of the lodgment of pieces of meat and bone in the œsophagus: and Dr. Stokes saw an instance in which a piece of money was lodged in the œsophagus and where croupy breathing and other laryngeal symptoms were manifestly the result. In this latter instance the foreign body was not lodged in the fauces or pharynx. I have myself seen cases to corroborate the above, but it is needless to swell this article with proofs of a pathological fact that will probably not be called in question.

It is probably a new observation—at all events it is one of great pathological interest, that spasm of the glottis may be produced by the presence of a foreign body lodged within the bronchi. In the month of May, 1836, a child was brought from the country and placed under the care of my friend Mr. Cusack: his father's account of the case was that he had swallowed a small pebble, was instantly seized with a violent paroxysm of cough, had croupy or sonorous breathing ever since the accident with occasional remissions and exacerbations, but was sometimes brought to the verge of suffocation. The stethoscopic indications were that the foreign body was loose and mobile within the trachea. I assisted Mr. C. in performing the operation of tracheotomy on this child; but, although the aperture in the windpipe was made very large, no stone was expelled, and the size of the organ did not admit of the employment of any forceps with which we were furnished. Immediately on the opening into the windpipe being perfected the croupy breathing disappeared, neither was there a severe paroxysm of cough experienced afterwards, and the father, either doubting that the foreign body had ever obtained admittance, or dissatisfied at its not being removed, carried him off to the country contrary to the wishes and advice of his medical attendants. We afterwards heard that the little pebble had been coughed up in about three weeks after he left town, but have not been informed as to the ultimate termination of the case.

On the 13th of September, 1839, a child, aged three years and a half, was brought to the Meath Hospital: he had, half an hour previously, swallowed a small stone, and was instantly seized with a violent cough which continued up to the period of admission. His breathing was quite stridulous—countenance expressive of great distress—face and lips lived—efforts at respiration hurried and gasping. The left side of the chest heaved violently, the right was comparatively quiet: respiration very weak and interrupted in the right lung, in the left loud and puerile: no dulness over either lung on percussion. I performed the operation of tracheotomy, but no foreign body was expelled, and yet the little patient experienced the greatest relief. The trachea was too small to allow of the introduction of any instrument for the extraction of the offending substance if such was there, so I merely satisfied myself with keeping the wound open, in the hope of its being coughed up. Whenever from any accident the wound in the throat became obstructed, the breathing became dreadfully oppressed, but he obtained instant relief when it was opened again and cleaned. Such were the phenomena of the case generally up to the 6th of October, when it was found that the wound had gradually closed and healed so as to leave the artificial opening very small, and on that day, in consequence of the increased difficulty of breathing, I was obliged to open up the whole wound anew. This second operation afforded immediate relief. On the 6th of December the wound being again nearly healed, in a desperate fit of coughing he expelled a small stone about half an inch long by about two lines broad, through the rima glottidis.

There were many other interesting facts connected with this case, which I omit here, my object being only to show that the difficult respiration which rendered the operation necessary was not caused by the mechanical occlusion of the bronchi by the presence of the stone, but had its seat in the larynx. The child had always repose when not called upon to employ the rima in respiration, although the stone was present in one or other of the bronchi, and in this case it was remarkable that it shifted its position, as proved by stethoscopic evidence.

It is sufficiently well known that the pressure of an aneurism, and of course of any other tumour, on the trachea or bronchi will produce difficult respiration to such an extent as to simulate laryngitis and to place the patient's life in imminent peril. This has been supposed to proceed from the mechanical obstruction given to the passage of the air by the compression of the tumour, and I shall not deny that this cause may occasion inconvenience, but still may be allowed to doubt that it produces the stridulous breathing and other laryngeal symptoms—at least in the majority of cases. In the month of July, 1837, I was requested by another practitioner to see a case of acute laryngitis and to operate if I deemed it necessary. The case appeared to be seriously urgent: the man seemed to be on the point of suffocation; and having made some inquiries as to the history, and particularly as to the condition of the chest as ascertained by auscultation, I operated immediately. The relief was as marked and as decided as I had ever seen in any laryngeal affection; and, after allowing the patient two or three hours' repose, I had him removed to the Meath Hospital, in order to be under my own immediate care. He died on the fourth day afterwards from the bursting of an aneurism of the aorta within the chest, and on examination the larynx was found in a perfectly healthy and normal condition; yet was it evident, from the relief experienced on the opening being made below it, that the obstruction to respiration that existed during life had been caused within this organ. Those who, with Le Gallois and Magendie, explain spasm of the glottis by a compression exercised on the recurrent nerves, may possibly consider that the aneurism in this case produced such pressure, and I am not in a condition to deny it, because the sac was collapsed and empty, and I could not say what pressure it might have created directly or indirectly when tense and full of blood. But the sac in no situation lay in contact with the nerve, or seemed to hold any relation to it that would lead to such a conclusion. I may add, incidentally, that I have seen aneurismal tumours which must have implicated this nerve, in which the spasmodic difficulty of breathing did not exist, and therefore whilst I believe that spasm of the glottis may be produced in consequence of, or in connexion with, the existence of some tumour compressing the trachea or bronchi, I cannot (in the present state of our knowledge) yield to the opinion that refers it so entirely to a compression of the recurrent nerve.

The ligaments of the larynx are, of course, liable to disease. Thus, during life, we argue on the possibility of an abnormal state of tension or relaxation, from observing certain alterations of the tone of voice which are thus supposed to be capable of being explained: but the most frequent morbid appearance found after death is ulceration, although there is no evidence of its ever commencing in these structures. In all cases of phthisis laryngea, the ligaments suffer severely and in some are actually destroyed; for the expulsion of the arytenoid cartilages by coughing is no infrequent symptom of that disease, and it could not otherwise occur. I have often imagined that this ulceration of the ligaments was one cause of the difficult respiration, particularly in cases where there is a marked difference between inspiration and expiration, by allowing to the arytenoid cartilages too great a degree of mobility, and permitting them to be thrown down on the rima. When the connexions between the cricoid and arytenoid cartilages are cut across posteriorly, it is easy to lay the latter down in such a manner as nearly to obliterate the rima; and if a similar division be effected by disease, why may not these little bodies, become loose, be acted on by the current of air and shut like a valve in every act of inspiration?

(W. H. Porter.)

LEG (Regions of the).—If the importance of a part, and the interest connected with the study of its structure and its diseases, be measured by the general amount of suffering through it entailed upon mankind, by its extreme liability to accident and injury, and by its value in the general movements and well being of the body, certainly the leg would possess claims to our consideration greater than any other portion of the system of the same extent. From the integument to the bone, and from the knee to the ankle, every part of it is the frequent subject of disease, more or less interfering with the comfort, if not with the health, of the entire system.

It is composed of two bones, the tibia and fibula, with accompanying masses of muscles both before and behind, which act upon the foot.

If we divide the leg into anterior, external, and posterior regions, we find in the anterior the tibialis anticus muscle, the extensor communis digitorum, extensor proprius pollicis, and peroneus tertius; in the external region, the peroneus longus and brevis; and posteriorly, the two gastrocnemii, popliteus, plantaris, tibialis posticus, flexor longus digitorum, and flexor longus pollicis. Among these are running the anterior and posterior tibial and peroneal arteries, with their accompanying veins, nerves, and absorbents; all these bound together, and supported by strong fascial coverings, and enveloped in the general integument. Between this and the fasciæ just mentioned, is an important layer of cellular tissue, (fascia superficialis,) enclosing the two saphenæ veins, major and minor, and the superficial nerves and absorbents.

It may be well to make some few observations upon the external form and characters of the leg, before describing the deeper seated parts. The leg, comprising all that part of the lower extremity between the knee above and the ankle below, is somewhat of a conoidal tapering figure, rather flattened on its anterior and outer aspect, full and round posteriorly. This shape renders permanent compression by means of a bandage very difficult. The contraction of the gastrocnemii, especially during walking, rarely fails in a short time to separate the turns of the bandage below, causing the lower ones to overlap each other, and producing constriction, irritation, and excoriation of the skin, above the malleoli. If this difficulty were more considered, and the importance of the bandage in diseases of the leg duly appreciated, we should see more pains taken in acquiring the art of its application than is now common; though we are happy to find that the minor operations of surgery are now beginning to receive much more attention than formerly, and to form a part of the general system of demonstrative instruction. Assuredly the aggregate amount of suffering relieved would be far greater by attention to these minutiæ of surgery, than by the more striking, though not more important details of operations, which to the mass of practitioners can occur but seldom, if at all.

The projection of the muscles at the back part of the leg, produced by the two gastrocnemii, and known under the name of the calf, forms a characteristic peculiar to man. No inferior animal possesses it, not even the ourang outang; and the feeble and uncertain gait of these animals, when in the erect position, at once demonstrates the value of the muscles of the calf of the leg, and that this position is natural only to man himself. The form and expression of this part of the leg varies much according to age, sex, and general habit. In infancy the gastrocnemii, in common with the developement of the whole lower extremity, are small and feeble. The upper extremities are, in early infancy, even larger than the lower; these latter do not acquire their full growth and proportions till adult age. In the female, the general form of the leg is less marked and prominent, and more rounded than in the male, while, in this last, the leg presents every possible variety of proportion, according as habits of exercise on foot, robust health, or long continued sickness, has invigorated or enfeebled the muscular system at large, or this portion of it in particular. The broad and rounded surface of the calf of the leg is contracting as it descends, and at the lower part projects like a kind of cord, representing the tendo Achillis. In contraction, the calf shows two portions, marked out by a double fissure, which indicates the situation where the gastrocnemius join the soleus, the lower elevation being formed by this last muscle, which extends lower down the leg than the gastrocnemius. This projection of the soleus is in some much more marked than in others, and is indicative of considerable power when it reaches lower down, much more so than when the whole prominence of the calf is high up. In persons celebrated for pedestrian powers we have observed this projection of the soleus in a marked degree.

In the anterior region of the leg, the form is considerably flatter than in the posterior, and narrows as we proceed downwards, at the lower part becoming almost round. During extension of the foot, this region is marked by longitudinal elevations and depressions, indicative of the situations of the muscles, and of the connecting portions of aponeurosis. An examination of these points will assist us in cutting down upon the arteries here, as the depressions mark the exact boundaries of the muscles, being produced by the aponeurotic processes, which dip between them.

The integument of the anterior region, generally covered with hair in man, and of a somewhat dense structure, enjoys sufficient mobility to admit of wounds being united by the first intention, provided the loss of substance be not great. Not being very extensible, abscesses, tumours, &c., have great difficulty in projecting externally in front of the limb, and consequently for the most part remain more or less flattened. The posterior part of the leg has an integument more soft and elastic, and possessing fewer hairs than the anterior, particularly on the inner side. The position of the skin, with relation to the parts which it covers, occasions a marked difference in the mode of repairing the ravages of extensive ulcerations or sloughings. On the front and outer part of the leg, where the skin is somewhat stretched over the tibia and fibula, the process of cicatrization can only draw together the sound parts to a small degree. In consequence the healing process is slower in completion, and the cicatrix less depressed in proportion than when it is situated posteriorly. On the contrary, in this latter situation, the skin being stretched only over soft parts, when a considerable portion of it has been destroyed, the contractile force of the new skin has full opportunity to exert itself, and this it does sometimes to a degree that is remarkable, acting as a sort of ligature upon the back part of the leg. We have seen a case where, by the cicatrization of an old and very extensive ulcer, the lower part of the calf of the leg, viewed in profile, had an appearance as if more than half the entire leg had been cut away.* The most dense and strong part of the integument of the leg is over the inner side of the tibia where this forms the only covering of the bone, while at the upper and back part of the leg the skin is exceedingly thin and delicate, and devoid of hairs. We may here remark, in illustration of the properties of the integuments of the leg, important in relation to surgery, that the contractile property of the skin is usefully exemplified in amputation, when, should the flap of the integument be more extensive than we desire, even to a great degree, we always find that in the progress of the case it contracts so much as to exhibit no redundance in the end; in fact that a large quantity of integument, however unsightly, is far less to be dreaded than the opposite defect. It is not our intention here to enter minutely upon the diseases of the parts we are now describing, but we cannot refrain from alluding to a state of disease of the integuments which we have never seen but in the leg, and of which we have met with no account in books. It consists in a soft elastic swelling, generally occupying the entire circumference of the leg, for the lower third or fourth of its length, though often much less. The skin over it is considerably redder than natural, and of a somewhat dark colour. It is not at all tender to the touch, but is exceedingly painful when the foot is down and in exercise; on pressing the finger firmly upon it no pit is left, but the skin is very white until the capillaries fill again, which they do slowly. Should the skin ulcerate, the sore is very slow in healing, and generally has a brownish unhealthy look, but the state in question often lasts for years without any ulceration occurring. The disease is very indolent, neither increasing nor diminishing in extent for many years. We have not been able to trace it satisfactorily to any cause more than too much standing. All the cases observed by us have occurred in females between the ages of twenty and forty, whose employment kept them very much on foot. It appears to us to consist in a varicose state of the capillaries of the cellular tissue and inner side of the cutis. No treatment that we have employed has had anything more than a temporary effect. Pressure, as long as it is continued, relieves it; but all the morbid symptoms return upon the remedy being omitted.

Immediately under the skin lies the cellular tissue, which is a part of the general cellular investment of the body, and is here known as the superficial fascia of the leg. It is generally pretty thick, and is easily dissected back in amputations. Placed between two solid layers, the aponeurosis and skin, it easily inflames and may become the seat of extensive inflammation and abscess. When the inflammation has terminated in gangrene, the sloughing process in this cellular tissue is very rapid and often very uncontroulable; and where this destruction has occurred to considerable extent, in the after process of reparation the new cellular web is so short, close, and inelastic, as to materially impede the freedom of movement in the limb. When pus has been formed, the facility which the loose texture of the superficial fascia offers for its spreading in all directions, points out the necessity for early and free incisions through the integuments; and even before this stage of the inflammation, and while it is in its most active state, the same bold practice offers us the best means of arresting its progress. This cellular layer is the seat of the effusion in phlegmonous erysipelas, anasarca, phlegmasia dolens, and partially so in elephantiasis. The distension which this tissue and the integument over it undergo in the diseases just mentioned, is occasionally enormous, and affords a striking contrast between the elastic properties of the natural and adventitious structures. When anasarca distends a leg upon which an old cicatrix exists, the newly formed cellular web of this part is so little elastic and so little admits the fluid into its cells, that a considerable depression is seen here in the midst of the general swelling.

Imbedded in this superficial fascia we find a number of veins which are various in size, none very large in the natural state, numerous, and here possessed of more surgical interest and importance than in any other superficial region of the body. They are principally arranged in two sets; one commencing about the inner ankle, and running along the inner side of the calf, terminates just below the knee by one trunk called the internal or major saphena. The other set form the saphena minor, by coming from the outer ankle, along the outer and back part of the leg, and terminating in the popliteal vein in the middle of the ham. This vein is superficial only in the lower two-thirds of the leg; after this, it passes through the layers of the aponeurosis, and runs under it till its termination. This is the more ordinary course of them, but no part of the circulating system is more various than these superficial veins in their divisions and arrangement. These veins, by becoming varicose, frequently occasion great suffering to the patient, and annoyance to the surgeon, by the difficulty of their cure. The saphena major is more liable to this state of disease than the minor; indeed few persons whose habits are to be much in the erect posture appear to attain middle age without being more or less troubled by it.

The deeper seated veins, which accompany the arteries, lie imbedded among the muscles, and from them receive considerable *passive* support, in sustaining the weight of the column of blood above them, and still more in an *active* sense, when, in contracting, the muscles swell and press against their sides, and thus assist in forcing onwards their contents. But these

* See article CICATRIX.

superficial veins are without this important help. Their sides are supported, on one hand, by the yielding layer of the fascia and muscles, and, on the other, by the integument. When, therefore, any impediment presents itself to the free transmission of the blood through the femoral, popliteal, or iliac veins, or even by the mere weight of the ascending column of blood, in persons who stand much, it is the superficial veins that suffer most, and a permanently dilated state is the frequent result.

The pathology of varicose veins has not received the attention which it deserves, and hence the conflicting opinions as to the precise nature of their origin; we must even now confess with Delpech that the nature and causes of the disease are unknown. It is quite clear that that state of disease of the veins commonly termed varicose comprehends more than one pathological condition, and probably has more than one mode of origin. Every instance of an enlarged vein cannot be considered as a varix, unless we confound under the same denomination a condition of the vessel natural and healthy except in regard to its size, neither originating nor terminating in a morbid condition, with every variety and degree of disease accompanied with enlarged capacity of the vein. We have seen the veins of the abdomen enlarged so as to fulfil the office of the vena cava inferior, which was obliterated. But there was not the slightest mark of disease in these superficial vessels. The uterine veins, also, in pregnancy become enlarged in a similar manner, thus answering to the call for the increased circulation of blood in the uterus. This state of the vessels has been aptly termed hypertrophy, and the term varix has been restricted to permanently dilated states of the veins, attended with the accumulation of dark blood, which more or less generally becomes coagulated and adherent to the parietes of the vessels. Of this latter species Andral enumerates six varieties: 1st, simple dilatation without any other change, such dilatation affecting either their whole length, or occurring at intervals; 2d, dilatation, either uniform or at intervals, with a thinned state of the veins at the dilated points; 3d, uniform dilatation with thickening of the venous coats; 4th, dilatation at intervals with thickening of the dilated points; 5th, dilatation, with the addition of septa within the vein, whereby the cavity is divided into little cells in which the blood lodges and coagulates; 6th, a similar disposition combined with perforations in the parietes of the veins, which communicate with the surrounding cellular tissue in a more or less diseased state by numerous small apertures. From repeated observation of its practical importance we should be inclined to add to this list one other variety, viz. when the varicose state had extended into, or existed distinctly in, the capillaries of the skin. We believe that in those troublesome ulcers known as varicose we shall frequently, if not generally, find this state of the minuter veins and capillaries, and we are more inclined to attribute the pain and the obstinate character of these ulcers to the pathological condition now mentioned than to the mere vicinity of an enlarged vein as it passes through the superficial fascia. The causes of the diseased state in question have been variously stated, nor do opinions yet agree upon it, some attributing it to mechanical influence, and others supposing a morbid tendency. Both these causes probably act in different instances, or even cooperate in the same case; we shall now only mention in illustration of the effect produceable by the mechanical influence of too much standing, that it is not necessary to suppose that the valves are either destroyed or even materially injured in structure to nullify their agency in supporting the column of blood above them, since ever so small a communication between the two columns, the upper and the under, is sufficient to destroy all the beneficial agency of the valves as supporters of the gravitating fluid in the veins. Therefore a dilatation of the vein merely enough to draw the opposed edges of the valve ever so little apart, or even a thickening of the valves preventing the accurate coaptation of their edges, will be sufficient to prevent their power of support to the superincumbent column, and as far through the vein as this defective state of the valves may exist, so far will the gravitating column of blood be virtually unbroken and entire, and in the same proportion will the tendency to the varicose state be increased. This reasoning will explain many, probably the majority of cases where the morbid dilatation having once begun goes on to increase rapidly by the continued operation of this exciting cause. That there are other causes capable of producing this state of the veins cannot be disputed; indeed the occurrence of it in parts not likely to be affected by the upright position, and even in several different parts of the body of the same subject, shews that there is occasionally a morbid tendency in the venous system to this particular state, which acts independently of any mechanical cause; but we believe that this predisposing cause is not necessary to the production of the disease, and that the morbid tendency, when it is met with, should be regarded rather as the exception than as the rule.

In considering the causes of the disease in question, we should not lose sight of the relative proportion of the deep and superficial venous circulations of the lower extremities, a proportion varying in almost every individual. In one, the superficial veins are large and numerous, and lie immediately under the skin; in another, they are few and small. It is obvious, that in the first case the blood retained by this route bears a large proportion to that passing through the deep set, much larger than it would in the latter case. In the first instance, therefore, these vessels will have a greater proportional weight of blood to sustain and transmit, than in the second; while, in those individuals who have the superficial circulation small, the blood is chiefly returned by the deep set, which, from circumstances before mentioned, are more equal to the task, and in such persons the diseased state in question rarely occurs. This we conceive to be a rational and practical explanation of phenomena which are otherwise obscure.

It seems probable that that most troublesome ulcer, the varicose, is kept up, and the difficulty of its healing produced not by the irritation occasioned by the mere vicinity of the enlarged veins, but from the actually varicose state of the capillaries of the skin at that part; at least we have found such a state of the vessels frequently, if not generally, to co-exist with this species of ulcer. The depth of the cellular layer (superficial fascia) in which these veins lie should be accurately understood and borne in mind in performing the operation of passing a needle under the vein for the cure of varices, according to Velpeau's plan (a method which we have adopted with considerable success.) Should the needle be passed so deep as to reach the fascia, the inflammation would probably be severe, at any rate sufficient to complicate needlessly the operation. The thickness of the cellular layer varies in different subjects, according as it is distended more or less with fat or with accidental effusion; it is rarely, however, less than two lines in depth, thus affording abundance of room for the transmission of the needle.

The size of these veins of the leg in the healthy state is at the most not larger than a small goose-quill, but when varicose they sometimes swell to the size of the finger, and we lately saw a varicose enlargement of the saphena major a little below the knee, of the size of a large hen's egg; the quantity of blood that may in a short time be lost from them may hence be conceived. On the anterior region the veins are few, and varices but rarely occur comparatively. On the inner region the saphena major lies close upon the bone in part of its course, and even indents it deeply when distention has continued long. In cutting upon the vein in this situation, we must bear in mind the contiguity of the internal saphenus nerve, whose situation, with relation to the vein, varies much, sometimes being before, sometimes behind it. We cannot, therefore, lay down any rule for its avoidance, unless it be to open the vein parallel to its length. The saphena minor has a nerve running with it, which in phlebotomy must be avoided with the same precaution as the nerve on the inner side.

The two *nerves* found imbedded in this superficial layer of the leg are, 1st, the internal saphenus, which is the largest, and is passing from the inner side of the knee to the inner side of the foot, accompanying the saphena major vein; 2d, the external saphenus or *communicans tibialis* from the tibial nerve, which runs near the saphena minor through the lower part of its course.

Imbedded in the superficial fascia, we also find a set of *lymphatics*, principally on the inner side of the leg, receiving part of those from the sole and dorsum of the foot, while those absorbents which accompany the saphena minor are receiving their commencement entirely from the sole of the foot. All of these superficial lymphatics ascend to the inner side of the thigh, and terminate in the inguinal glands. Hence diseases of the subcutaneous cellular tissue of the leg exert their influence upon the superficial glands of the groin, and are not unfrequently the cause of disease in them, which, without due inquiry, might erroneously be attributed to disease of the genital organs.

The *aponeurosis* of the leg forms an important part of its economy. It is a dense tendinous structure, which immediately invests the muscles, and partly affords them origin. In consequence of its strength and want of elasticity, it prevents swelling in deep-seated inflammations, and we are consequently obliged to divide it early and freely, particularly when suppuration already exists, and when the matter would otherwise burrow among the muscles. On the anterior region it is strong, very distinct, and tense. In its superior fifth, it gives attachment to the fibres of the tibialis anticus, extensor communis digitorum, and peroneus longus. Below, it is pierced by the anterior tibial and musculo-cutaneous nerves. It is attached above to the heads of the tibia and fibula, and along the crest of the tibia, stretching from this to the anterior edge of the fibula. At the upper third of the leg, it sends processes backwards between the muscles, to be attached to the bones, thus forming sheaths for the muscles, and affording to their fibres a greater extent of origin. At the lower two-thirds of the leg, the fascia is closely attached to the intermuscular tissue, but has here no septa from its own structure. At the lower third, it binds the tendons firmly down in their places, and by its transverse fibres opposite the ankle forms the anterior annular ligament of that part.* From the anterior edge of the fibula, this fascia passes over the two peronei muscles, and is again inserted on the posterior border of the bone, forming a sheath for these muscles, and dividing them from the soleus. The observations made above on the surgical treatment of purulent collections refer especially to this anterior portion of the fascia of the leg, on account of its greater strength, density, and inelasticity.

At the back part of the leg, the aponeurosis is a continuation of that of the ham. We may consider it as formed of two principal layers; one superficial, and the other deep. Attached to the posterior border of the fibula externally, and to the inner margin of the tibia internally, the first appears to arise from the expansion of the tendons of the sartorius, gracilis, and semitendinosus. Applied over the posterior surface of the calf, it is lost below in the fibro-cellular tissue surrounding the heel. This portion being thin and yielding, it allows deep-seated abscesses to become superficial with great facility. The second layer is a continuation of the aponeurosis of the popliteal cavity, and descends between the two layers of muscles; but splitting into two, at the point where the soleus detaches itself from the deep parts, one of its divisions follows the anterior surface of the

* See ANKLE-JOINT, REGIONS OF.

tendo Achillis, of which it completes the fibrous canal, formed posteriorly by the superficial layer; the other remains applied over the posterior surface of the deep muscles, and both arrive at the heel.

In its inferior third, this aponeurosis thus circumscribes three spaces. One is filled by the tendon of the muscles of the calf. The second incloses the flexor muscles of the toes, and the vessels. The third, which separates the two others, lies between the tendo Achillis and the posterior surface of the last-named muscles. The latter is remarkable, from being filled with fat and fibrous filaments, interlaced in various directions.*

We have, for convenience of description, detailed the anatomy of the superficial parts of the leg, without particular reference to the regional divisions, which become more defined, distinct, and practical as we investigate the relations of the deeper seated parts, and to which we shall therefore now limit ourselves.

In the anterior region, comprising all those muscles which rest upon the tibio-fibular fossa, we find, on dissecting the fascia from the upper part, only two muscles exposed, viz. the tibialis anticus and extensor communis digitorum. Lower down, we see in addition the extensor proprius pollicis coming out between the two last, and the peroneus tertius a slip of the outer side of the extensor communis. These four are, as it were, bound down in a canal, formed anteriorly by the aponeurosis, posteriorly by the tibia, fibula, and interosseous ligament. The direction of the tibialis anticus, its size, and boundaries should be borne in mind, as these form the surest guide for cutting down upon the anterior tibial artery. This muscle is of a prismatic form, tapering downwards, and its outer edge is indicated externally by a sulcus in the integuments made more apparent by extension of the foot. It is found more accurately by tracing a line from the middle of the space between the crest of the tibia and the fibula to the middle of the instep; and here, between this muscle and the extensor communis, the artery runs. The external muscles are the peronei longus and brevis; they are enveloped in a sheath of the aponeurosis, and are applied, for some extent, to the external surface of the fibula. They are completely separated from the extensors and from all the muscles of the posterior region by the two aponeurotic septa attached to the anterior and posterior edges of the bone. The adherence of the muscular fibres continuing until just above the outer malleolus, a transverse section, in the two superior thirds, does not entirely destroy their action upon the foot, while, lower down, it would render abduction almost impossible. We have not heard of an instance of the entire rupture of any of these muscles, nor is it an accident likely to occur, as they are not, from their situation, likely to be called upon for any very great exertion of power; but these muscles are occasionally liable to the accidental rupture of some of their fibres, a circumstance attended with much more pain and distress in moving than the apparently slight nature of the accident might lead us to expect. We have had lately a case of this kind under our care, where the suffering and the injury to the movements of the foot were so great as at first to lead us to suspect a much more serious extent of injury than really existed. It was occasioned by attempting to push along a sack of corn with both knees, both feet being on the ground, and the heels raised, while the upper part of the sack was held in the arms.

The only artery of importance in this region is the anterior tibial. It commences from the trunk of the popliteal nearly at right angles, traverses the opening in the upper part of the interosseous ligament, close to the neck of the fibula, and below the head of the tibia. The angular curve which the artery makes at this part of its course, according to M. Ribes, accounts for the great retraction of it after amputation of the leg.* It descends upon the interosseous ligament, in the direction of a line drawn from the middle of the space between the head of the fibula and the crest of the tibia, to the middle of the instep. Through the upper part of its course it lies upon the interosseous ligament; as it descends it gradually advances upon the tibia, and runs upon the anterior surface of this bone through its lower third. It is found at the upper third of the leg, between the tibialis anticus and extensor communis digitorum; in the middle third, its course is between the tibialis anticus and the extensor longus pollicis, and about four inches above the ankle-joint it passes obliquely under the tendon of this last muscle, and then is found between its tendon and that of the extensor communis. It runs between two veins through its whole course. The nerve is on its outer side above; in front in the middle; and internal below. An extensible but resistant cellular sheath unites the whole. It is evident, that in the upper part of its course the artery will be found much deeper than at the lower, when it is lying among the tendons, but in the living subject the natural state of tension of the muscles keeps these tendons more elevated than after death, and we shall consequently find the artery, even in this situation, deeper than from dissection we might have been led to anticipate. The surgeon will find little difficulty in discovering this artery when it is required to be tied. The marks for his guidance are clear, and the situation of the vessel on the whole pretty uniform; but owing to the depth of its situation above, and to the immediate vicinity of the veins and nerve, some difficulty will be experienced in excluding these from the ligature. The only branch from it of any surgical importance is the recurrent tibial. This arises just after the trunk has passed through the interosseous ligament, and passes upwards in numerous branches to the parts below and to the outer side of the knee-joint, anastomosing freely with the inferior external articular artery. These

* See Velpeau's Anatomy of Regions, translated by Hancock.

* See Velpeau's Anatomy of Regions, p. 473.

anastomoses form an important part of that system of collateral circulation by which the stream of blood is continued to the leg and foot, after the obliteration of the popliteal artery.

The anterior tibial artery may require to be tied in case of wound or aneurism. In wounds of the dorsal artery of the foot, it may be advisable to put a ligature at the lower third of the leg, when the anterior tibial is running between the tendons. Its course may be here ascertained by feeling its pulsation, or by observing the line of the tendon of the extensor proprius pollicis, on the fibular side of which it here lies. When about to tie it higher up, the incision in the integuments and fascia must be the more free in proportion as it is nearer the knee; and it may sometimes be advisable even to divide some of the fibres of the fascia transversely, to permit more freely the retraction of the muscular sides of the cut. In dissection, we so easily separate the muscles and expose the artery, that we may underrate the difficulty attending the operation of tying it. The depth at which it lies in this part, the constant contraction of the muscles, and the difficulty of retracting the sides of the incision, occasioned by the strong aponeuroses, all constitute considerable obstacles to the operation. This artery was subcutaneous in a case related by Pelletan, and is occasionally very small indeed, or even absolutely wanting. The first anomaly we have several times seen in dissection, and an instance of the latter is related by Huguier.* In these cases a large branch of the peroneal, which had passed through the interosseous ligament a little above the ankle-joint, supplied the place of the lower part of the artery. In a case which was met with by Velpeau, he found this artery not perforating the interosseous ligament at all, but winding round the fibula just below the head of this bone, and in company with the musculo-cutaneous nerve.†

The artery is accompanied by two veins, one placed on each side, throughout its course. The anterior tibial nerve, which is a branch from the peroneal, runs on the fibular side of the artery first, and then obliquely crosses it, sometimes again passing outwards, towards the lower part of the leg. The deep-seated lymphatics following the course of the vessels, deep-seated disease of the front of the leg may produce alteration of the glands of the ham. A lymphatic gland is found in front of the anterior tibial vessels, a little below the opening of the interosseous ligament through which the vessels pass.

In the posterior region of the leg the muscles are arranged in two distinct layers, the superficial, composed of the gastrocnemius, soleus, and plantaris; the deep, of the popliteus, the tibialis posticus, the flexor communis digitorum, and flexor longus pollicis. The gastrocnemius becomes tendinous, considerably higher in the calf than the soleus, sending off its broad thin tendon about the middle of the leg, to unite with that of the soleus, about the junction of its middle and lower thirds. The soleus, beginning its origin lower than the last muscle, from the bones of the leg, continues its muscular fibres lower in proportion, in this respect varying considerably in different subjects.

These two muscles, arising above by their distinct heads, and having but one insertion below, form in fact but one muscle, which Meckel has named the *triceps suræ*. Their common tendon is of a strength proportioned to that of the muscles themselves, and is therefore exceedingly powerful. Notwithstanding, the combined action of the muscles is occasionally too much for the tendon, and in leaping, dancing, or other similar movements, it is sometimes ruptured. After this accident, the difficulty of cure results, not so much from the injury done to the tendon itself, as from the difficulty of bringing the two ends into apposition. In fact, complete union never occurs, the utmost extension of the foot never bringing the lower portion so high as the upper is retracted by the muscles. The union, however, which is of a cellular structure, becomes sufficiently strong to be perfectly serviceable. Boyer speaks of a partial rupture of the tendo Achillis, and describes with precision the symptoms, but we apprehend this form of the accident is very rare.* The pathology of club-foot, which has only of late years been clearly understood, shows that permanent retraction of the muscles of the calf, either primary or secondary, is its most frequent cause, and the division of the tendo Achillis and the other tendons of this part has in consequence been resorted to with great success.† The plan of operating which our experience leads us to prefer, is to insert a sharp-pointed bistoury through the skin, and pass it behind the tendon with its flat side towards it, till having reached its farther side, the edge is turned, and the tendon is divided in the withdrawal, without more division of the skin than the mere puncture. If the tendon is kept tense during the operation by the forcible flexion of the foot, and is not quite divided at one stroke, the undivided tendinous fibres are pulled and stretched, and partially torn from their lateral attachments, which occasions a sort of hissing noise, which is not heard when the force is not applied, till after the entire division of the tendon. The union here takes place in the same manner as in rupture of the tendon, but the treatment proceeds upon a somewhat different principle, since it is in this latter case the intention to keep the divided ends apart, and the foot is therefore placed at right angles, while, in the ruptured tendon, the foot is extended, in order to approximate the ends as much as possible. The extreme contraction of the muscle, in club-foot, leaves no possibility of further retraction of the upper part of the

* See Boyer's Maladies Chirurgicales, tom. ii. p. 95.
† See Liston's Practical Surgery, p. 154.

tendon, therefore the whole separation, after the division, is performed by the moving of the lower part.

The powerful muscles, now described, are never known to be ruptured themselves, the tendon, as we have seen, yielding first, but a partial rupture of their fibres is not very uncommon, and is indicated by the same painful symptoms as were alluded to in speaking of the anterior muscles. It is worth remarking, on the great power of these muscles, that, great as is the force required, to elevate the whole body, by acting upon the heel, yet the muscles of the calf are not nearly so soon fatigued in walking as those on the front of the leg, whose labour is merely the elevation of the foot and toes, and of this every one must be sensible after unusually long exercise on foot.

Between the gastrocnemius and the soleus is the plantaris tendon, a long slender slip, which, after crossing between the muscles, runs on the inner side of the tendo Achillis, to its insertion. The belly of this little muscle is under the outer head of the gastrocnemius, close to the origin of which it arises. Authors describe the symptoms attendant upon rupture of this tendon, but the diagnosis of injury to so small and deep-seated an organ must be so uncertain, that we should be much more inclined to refer them to an injury of some of the fibres of the great muscles of the calf, especially when we compare the power of the plantaris with that of its tendon, the passive strength of the latter appearing greatly superior to the active force of the former.* Between the lower part of the tendo Achillis and the tendons of the deep layer of muscles, there is a considerable layer of cellular tissue, containing fat, and this is often the seat of troublesome chronic inflammation; and if suppuration follows, the abscess is often very difficult of healing, from the constant movement of the tendon, and the result is a troublesome sinuous ulcer, which can only be healed by keeping the foot entirely at rest.

The deep muscles, bound down in the posterior interosseal space, by the inter-muscular layer of the aponeurosis, are found lying in this order; the flexor digitorum communis, placed innermost, upon the back of the tibia; the flexor longus pollicis, on the fibula, and the tibialis posticus between them, and partly concealed by them. Upon this last muscle are situated the posterior tibial vessels and nerves. As they all of them have to pass nearly behind the inner ankle, the two outermost are gradually approaching to the flexor communis, as they descend, till they are nearly in contact one with the other. As all these tendons, either primarily or secondarily, act upon the ankle-joint, their action is retained after rupture or division of the tendo Achillis, so that the power of extension of the foot still remains, though in a feeble degree.

The arteries of this region are the posterior tibial and peroneal, and are given off from the termination of the popliteal. The anterior tibial also has here a course of a few lines, from its origin, till it perforates the interosseous ligament. The posterior tibial may be considered as the continuation of the trunk of the popliteal. It commences about an inch below the origin of the anterior tibial, and where the popliteal divides into this artery and the peroneal. The course of the posterior tibial may be defined by a line drawn from the middle of the ham, to a spot half an inch behind the inner malleolus. In this course it is accompanied by two veins, one on either side, also by the posterior tibial nerve; in the upper part of the leg, this nerve lies to the inner or tibial side of the artery; it soon, however, passes over it, and inferiorly it lies to its outer or fibular side.

The posterior tibial artery is covered, in the upper and middle thirds of the leg, by the gastrocnemius and soleus muscles, but in the lower third only by the integuments, and by the superficial and deep fasciæ of the leg. In the upper third of its course, this artery rests upon the tibialis posticus muscle, in the middle third upon the flexor digitorum communis, and in the inferior third some fat and cellular membrane separate it from the tibia, and from the internal lateral ligament of the ankle-joint.

In the inferior third of the leg, the posterior tibial artery runs nearly parallel to the inner edge of the tendo Achillis; between the os calcis and malleolus internus, it lies nearly in contact with the sheath of the flexor digitorum communis.* The only branch of surgical interest given off by this artery in the leg is the nutritious artery of the tibia, which comes off about its upper third, and in amputation at this part sometimes bleeds freely.

In putting a ligature upon this artery, the difficulties attendant upon the operation vary according to the situation at which we seek for it. It is favourably circumstanced for operation in the inferior third of its course, being covered in the two upper thirds by the muscles of the calf. It may require to be tied for a wound in the sole of the foot, or for one behind the inner ankle. In either of these cases the artery may be found and tied with facility behind the inner malleolus. (See Ankle-Joint, Region of.) When, however, it is deemed desirable to tie it at the lower third of the leg, it will be readily found by an incision of from two to three inches in length, performed midway between the inner border of the tibia and the tendo Achillis. After the division of the integuments, the superficial fascia, and the deep fascia, the artery will be met with directly under the incision. Its accompanying veins sometimes completely conceal it; the nerve is here on the fibular side of it.

In case of secondary hæmorrhage after this operation, or in case of aneurism of the posterior tibial artery, forming in consequence of a wound of the artery in this situation, it may be necessary either to tie this vessel higher up in the leg, or to tie the popliteal femoral artery itself; it has been deemed prudent to give the patient the chance of success from the former

* See Dictionnaire des Sciences Medicales, article Jambe.

* See article Ankle-Joint, Region of.

operation, before having recourse to so severe and hazardous a measure as that of tying the femoral or popliteal artery.

The operation of tying the posterior tibial artery in the middle of the leg will be found much more difficult than either of the other situations mentioned, as this vessel here lies at such a depth from the surface, and is covered by the gastrocnemius and internal head of the soleus, which in this situation is attached to the tibia. To expose the artery here, the leg should be bent, the foot extended, and both laid on the outer side. The incision must be of considerable length, not less than four inches, along the inner edge of the tibia. The integuments and fascia being divided, (care being at the same time taken to avoid the saphena vein,) the edge of the gastrocnemius muscle will be exposed; this will be easily raised and drawn to one side. The soleus must next be divided from its attachment to the tibia, and at the bottom of this incision will be discovered some dense aponeurotic fibres, which are part of the deep fascia of the leg. The muscular fibres in the incision must now be held wide apart, and carefully separated from this deep fascia preparatory to its division, and immediately underneath this fascia lies the artery, with its accompanying veins, one on each side, with the nerve on its inner or tibial side, and here situated about an inch from the edge of the tibia.

On the dead subject this operation is not attended with much difficulty; in the living, however, the case is very different; the muscles are then rigid and unyielding, and when the fascia which covers them is divided, they leave their natural situation, and become much elevated, so as to make the situation of the artery appear as a deep cavity, at the bottom of which the vessel is placed. The contraction of the muscles has been found in some cases so great an impediment to the operation, as to require the transverse division of part of the muscle. The operation of cutting directly from behind, through the fibres of the gastrocnemius, is obviously still more objectionable, from the cause just mentioned.

The second terminating branch of the popliteal artery is the peroneal. This is situated deeply, along the posterior part of the leg, taking the direction of the fibula; hence it is sometimes called fibular. It commences about an inch or two below the lower border of the popliteus muscle, after perforating the tibialis posticus at the commencement of its course, and descends, almost perpendicularly, towards the outer ankle. In this course, it lies close upon the fibula, between the flexor proprius pollicis and flexor digitorum communis. On reaching the lower extremity of the interosseous ligament, it divides into two branches, the anterior and posterior peroneal, the first of which passes through the aperture at this part of the interosseous ligament, and both of these run to the outer side of the foot. This artery is so small and so deeply seated, that its wounds are rare and unimportant. Hence but little has been said of its ligature, which would be very difficult, and could only be performed at the middle of the external side of the leg. We should then divide the same parts as for the tibial, but on the opposite side, and as it is enveloped in the fibres of the flexor longus pollicis, we must also detach this muscle from the fibula.

Each of these arteries of the posterior region is accompanied by two veins, which frequently overlap the artery so as to conceal it from view, in the operation of securing it; they are also so adherent to its coats as to occasion some difficulty in separating them, so as to avoid including them in the ligature, particularly where the artery, as in the present instance, is deep-seated. The best mode of accomplishing this is to insinuate the aneurismal needle first on one side, and then upon the other, not attempting to bring it out on the opposite side of the artery, till, by this means, the lateral attachments are separated.

The deep nerve which accompanies the posterior tibial artery is the tibial, and is of considerable size, being the continuation of the trunk of the popliteal. It is situated, at first, to the outer side of the artery, and lower down it runs nearly behind it, and so close to it, that without care it may be injured, included in the same ligature, or even tied for that vessel.

It may not be amiss here to observe on the distinctive marks by which the nerve may be recognized, when passing the ligature under the artery, that besides the most essential, the absence of pulsation, which may occur even to the artery itself from accidental causes, the inexperienced operator will find considerable assistance from the following, viz. the firm, round, cord-like feel of the nerve, while the artery has a flattened yielding feel when pressed between the finger and thumb, and the whitish, somewhat glistening, and prominent round appearance of the nerve, the artery having a somewhat reddish colour, and a flattened, thick, and riband-like appearance, as it is raised upon the aneurism needle. When the cut extremities of the two are seen together, after an amputation, of course the round open mouth of the one, and the prominent stump of the other, like a tight packet of thread cut across, are readily recognizable.

The lymphatics of these deep parts accompany the bloodvessels, and pass to the glands of the ham; hence diseases occurring in the parts beneath the aponeurosis of the leg exert their influence on the glands of the popliteal space.

The two bones of the leg united by the interosseous ligament form an elongated fossa in front which is closed in by the aponeurosis, and is larger at the union of its two superior thirds than at its extremities. The muscles being imbedded here are difficult to cut in circular amputations, at the same time that its depth prevents the formation of a good flap. Posteriorly, they form a gutter, or fossa, larger than the preceding, but also much more shallow, excepting at the lower part. Hence the deep muscles are easily comprehended in the flap in amputation. In the circular operation the section of the flesh, which can only be effected by passing the point of the knife transversely over the bottom of the interosseous fossæ, is equally difficult in the flap method, in making the anterior flap, in consequence of the depth of the space in which the muscles are lodged. The difference of size of the two bones and the posterior relative situation of the fibula renders some precaution necessary in dividing them with the saw. The foot must be turned in, so as to bring the fibula a little forward, and care must be taken to commence the section upon the tibia as being the longest and strongest, but to finish the section of the fibula first, since it is too thin and mobile to support the movements of the saw without breaking at the termination. In amputation above the tubercle of the tibia, it has been held advisable to remove the head of the fibula from its joint, since this small portion of the bone is of no advantage to the stump and by its mobility may be some hindrance in the after treatment. (See Knee-Joint.)

The small size and moveable nature of the fibula constitutes some difficulty in the treatment of fractures of the leg, since the application of the ordinary bandages, &c., would have a tendency to press the bone inwards against the tibia, and we not unfrequently see, in old united fractures of these bones, this deformity to have been produced, in all probability, from want of due precaution in the application of bandages. The defect may be obviated by proper care, that neither the splints nor the cushions should take any bearing upon the fibula itself except at its two extremities, and great assistance may be derived from proper pressure, before and behind, upon the muscles, gently forcing them against the interosseous ligament and bearing outwards the bone attached to it.

After amputation of the leg, the tibia presents a triangular surface, having the apex forwards. As the skin covering it is hereby invested with the subcutaneous layer, it may, by pressure against this projection, ulcerate, or slough, and thus expose the bone. The great means for obviating this accident is to have a good supply of integument in the flap, so that, in bringing the parts together afterwards, they may not be drawn too tight over the bone. While this rule is attended to all will go on well, whereas when the integument is left scanty, nothing can prevent unpleasant consequences. It may often, however, be advisable to remove with the saw the projecting angle of bone, and as a matter of precaution we generally do this, though not attaching much importance to it.*

In amputating above the tuberosity of the tibia, we run the risk of opening into the knee-joint, as the synovial membrane is sometimes prolonged thus far. According to M. Lenoir the synovial cavity of the knee is continuous with that of the superior tibio-fibular articulation, once in four times.† There are always three principal vessels to be tied in this operation: first, the anterior tibial, which is found, with its collateral nerve, close upon the interosseous ligament; secondly, the posterior tibial, in contact with the deep layer of the aponeurosis, and having its nerve to its outer side; and, thirdly, the peroneal, which is found imbedded in the flexor longus pollicis muscle, and may be readily tied without fear of injuring any nerve. These three arteries sometimes retract so far into the flesh after amputation, that to secure the anterior tibial it is necessary to cut through the interosseous ligament to the extent of some lines. This probably arises principally from the attachment of the muscles to the whole parietes of the interosseous fossa, while the vessels, enveloped by elastic cellular tissue, retract considerably.

It must be borne in mind, that in whatever situation the amputation may be performed, if it be the flap operation the arteries of the flap are much more difficult to be found and secured, owing to the oblique nature of the section, than where, as in the circular operation, the muscles and vessels are cut transversely through.

When the amputation is just below the tuberosity of the tibia, the nutritious artery has here sometimes a volume sufficient to require a ligature. With the exception of this last, the arteries to be tied will be nearly the same, in whatever part of the length of the leg the amputation is performed. The muscular branches seldom occasion much inconvenience from hæmorrhage.

It may not be out of place here to remark on the subject of amputations of the leg, that the division of the bones high up may often save the knee, and thus give a good bearing for a wooden leg, but that we are too often apt to act upon the principle that, in amputations below the knee, this joint must necessarily be the bearing point; whereas we are convinced that a much more useful stump is gained by saving as much as possible of the leg, at least as far as half of its length, with the view of applying the wooden leg to the stump itself, and so preserving entirely the use of the knee-joint. We have now adopted this plan, with the most perfect success, in several instances, and always to the great comfort and satisfaction of the patient. Indeed, the loss of the limb, which is thus remedied, is really little felt, when compared with the great inconvenience of making the knee the bearing point, and thus taking away all the benefit of it as a joint. The reason why this mode of operating has not been more generally adopted, appears to us to consist in the fear that the cicatrix of the stump is ill able to bear the weight of the body in walking, when pressed between the ends of the two bones and the artificial leg. But besides that by the flap amputation in the middle of the leg, (the best possible situation for this operation, when practicable,) a soft cushion of muscle can be added to the integumental covering to obviate the effects of pressure, the fact is that in the application of the artificial leg to this stump, the bearing is not entirely

* See Bell's Operative Surgery, vol. ii. p. 22.
† See Velpeau's Anatomy of Regions, p. 484.

upon the stump itself, but it is divided between this and some part of the anterior surface of the leg, generally falling most powerfully about the tubercle of the tibia. The bearing on the anterior part of the leg is so strong, that unless the precaution is taken of well padding that part of the wooden box, the pain occasioned by the pressure entirely prevents the use of the wooden leg; but by the use of this precaution all inconvenience is obviated, and by this support to the weight of the body a valuable help is found for the prevention of injury to the cicatrix of the stump.

The French surgeons used to recommend this mode of applying the artificial leg, but only in cases of conical stump, or at least where the integuments were from excess of inflammation after the amputation closely adherent to the bones.* But we have found it applicable to every case of amputation below the knee. The superiority which this wooden leg gives to amputations below the knee over all those at the ankle and through the joints of the foot is obvious. Besides saving the extra pain and risk of inflammation, it affords a much better point of support than the mutilated foot can form.

The anterior surface of the tibia being subcutaneous, and not covered by any artery of importance, indicates the region which should be chosen for exposing, when we would remove a portion, trephine, extract sequestra, balls, &c. Superiorly, as its external region is only covered by the origin of the tibialis anticus muscle, it is favourable to the same operation. This consideration is the more important since the publication of the very valuable observations of Sir B. Brodie on abscess in the cancellated structure of the tibia, a disease which till then was little understood and scarcely at all described, and which, from our own experience, we are inclined to think has not unfrequently cost the patient a limb, which by a more correct knowledge of the disease might have been saved.†

The periosteum of this anterior surface is the subject of troublesome inflammation more frequently than that of the other parts of the bone, in consequence of its greater exposure. Common inflammation of it is often productive of abscess, necrosis, &c., or in a scrofulous diathesis, of caries; while syphilitic inflammation is here showing itself in the form of nodes, occasioning great trouble to the surgeon and suffering to the patient, and generally leaving some permanent thickening. These nodes, which, as we have said, generally occur on the anterior surface of the bone, are sometimes thrown out upon the external and posterior parts, and when they do thus occur are doubly embarrassing to the surgeon from their deep situation among the muscles, and from the general similarity of the symptoms to muscular rheumatism; the extreme tenderness of the periosteal inflammation, much more acute than that of rheumatism, and the more circumscribed nature of this tenderness, are signs which will facilitate the diagnosis, a subject, however, upon which it is not here the place to dilate.

In the fœtus, the tibia presents merely a slight curve anteriorly, which appears to be augmented in the adult by the weight of the body. The posterior muscles, stronger and more numerous, acting on the flexible bones, concur to the same end. Thus, in fractures, particularly from indirect causes, the angle formed by the fragments of the tibia is almost always in front, and the limb bends in the situation of the fracture.

Experience proves that the two bones of the leg are more frequently broken together than singly, a fact ascribed by Boyer to the strength of the knee and ankle-joints. The direction of an oblique fracture of the tibia is generally from below upwards and from within outwards, a circumstance due to the form of the bone. The end of the upper fragment then presents itself under the skin, at the front and main part of the leg. The most frequent situation of fracture of either of the bones of the leg is at the lower third; this, in the tibia, is readily accounted for by its being here more exposed to injury and being smaller and weaker than elsewhere; in the fibula, on the contrary, this part is not weaker, but is here placed more superficial, the upper part being completely covered and much defended by a cushion of muscle. Fractures of the tibia at its upper part are less liable to displacement than lower down on account of the greater thickness of the bone, but the vicinity to the knee-joint here increases the danger of a fracture considerably. In consequence of the thickness of the bone at this point, fractures here are ordinarily transverse, while the abundance of spongy tissue causes them to unite quickly and easily. The tibia is more frequently broken by itself than the fibula because it alone sustains the whole weight of the body, while the fibula has nothing to support. In fact if the fibula is generally broken at the same time with the tibia, the injury to the fibula is but subsequent to the other, and takes place because this slender bone is not capable of bearing the weight of the body, the impulse of external violence, or even the action of the muscles, after the tibia has given way.*

There is rarely much displacement, as regards the length of the bones, at whatever point their fractures may have occurred, unless the cause has continued to act after the solution of continuity. This appears to result from the muscles being inserted over the whole of the bony surfaces.

When the fibula alone has been broken, there is very little deformity resulting, as the principal support of the limb still remains, particularly if the injury has resulted from external violence. When however the cause

* See Dictionnaire des Sciences Médicales, Art. Jambe.

† See also some excellent practical observations on the subject in Liston's Elements of Practical Surgery, p. 95.

* See Cooper's Surgical Dictionary, article Fracture.

of the fracture is found in a violent twist of the ankle with dislocation, the deformity occasioned by this state of the joint is more or less considerable, according to the degree of this displacement.

(A. T. S. Dodd.)

MUSCLES OF THE LEG.—The muscles lying on the bones of the leg, both before and behind, are, with the exception of one, properly muscles of the ankle-joint and foot, since their primary action is exclusively upon these parts. (See article FOOT, MUSCLES OF.) For the convenience, however, of description they will here be demonstrated according to their situation.

The muscles of the leg may be classed into anterior, external, and posterior. The anterior lying in the space between the tibia and fibula are four in number, consisting of tibialis anticus, extensor proprius pollicis, extensor longus digitorum, and peroneus tertius. The tibialis anticus and extensor longus alone are seen at the upper part of the leg on removing the deep fascia; the extensor proprius pollicis emerging from between these muscles about one-third down the leg, and the peroneus tertius shewing itself as a separate slip of the extensor longus, about the same height, and at its fibular side.

1. *Tibialis anticus* lies upon the fibular and anterior surface of the tibia; *arises*, principally muscular, from the fibular side of the tibia, through its two upper thirds, from its tuberosity and spine, and from a small portion of the interosseous ligament, from the fascia of the leg, and from an aponeurotic septum placed between it and the extensor digitorum longus. The muscle is larger above than below; its fleshy fibres converge to a strong tendon which crosses from the outside to the fore part of the tibia, passes through a distinct ring of the annular ligament near the ankle, runs over the astragalus and os naviculare, and is *inserted* into the upper part of the os cuneiforme internum, and base of the metatarsal bone of the great toe. The insertion of the tendon is concealed in part by the adductor and flexor brevis of the great toe. Between the tendon of this muscle and the os cuneiforme we find a small bursa mucosa. This muscle is covered in front by the fascia of the leg, to which it adheres superiorly; behind it is in contact with the tibia and interosseous ligament, on the fibular side with the extensor digitorum communis, and extensor proprius pollicis. Its action is to flex the foot upon the leg by elevating the anterior part of the foot.

2. *Extensor longus digitorum.*—This muscle occupies the fibular side of the tibio-fibular fossa, as the last filled the inner side. This is a tapering muscle also; it *arises* tendinous and muscular from the fibular or outer part of the head of the tibia, from the head of the fibula, and from the anterior angle of that bone almost its whole length, and from part of the tibial side of it also; it also takes origin from the interosseous ligament, from the fascia of the leg, and from the aponeurotic septum situated between this muscle and the last. Below the middle of the leg it splits into four tendons. These pass under the anterior annular ligament in one common sheath with the peroneus tertius. They then run along the dorsum of the foot, spreading as they go, and are *inserted* into the root of the first phalanx of each of the four smaller toes. Towards their termination each of the tendons expands into an aponeurosis, covering the upper surface of the phalanges, and this is strengthened by the tendons of the extensor brevis and gives attachment to the lumbricales and interossei.

This muscle is covered in front by the fascia of the leg, the annular ligament and the integument; posteriorly it rests upon the fibula, the interosseous ligament, and the tibia; externally it is in relation with the peronei muscles, internally with the tibialis anticus, and extensor proprius pollicis; along its lower and fibular border lies the peroneus tertius. On the dorsum of the foot its four tendons cross obliquely over those of the flexor brevis digitorum.

Action. To extend all the joints of the four smaller toes, and to bend the ankle-joint.

3. *Extensor proprius pollicis* lies between the two last muscles. Its origin is hidden by them. It commences about one-third down the leg, from the smooth surface of the fibula, between the anterior and tibial angles of that bone, of which surface it occupies part, through the middle third of its length, also from the lower two-thirds of the interosseous ligament. The fleshy fibres run obliquely forward into a tendon placed at the anterior border of the muscle, which after passing beneath the anterior annular ligament, and along the dorsum of the foot, is inserted into the bases of the first and second phalanges of the great toe.

Action. To extend the great toe, and to bend the ankle.

By its fibular side this muscle is in relation with the extensor digitorum communis; by its inner side with the tibialis anticus and anterior tibial vessels. The anterior border is covered by these two muscles, as low as about the middle of the leg, and inferiorly by the anterior annular ligament, under which it passes in a separate groove, and by the integuments. The posterior border rests upon the fibula and interosseous ligament, and it crosses in its course over the lower end of the tibia the ankle-joint, the anterior tibial vessels, and dorsum of the foot.

4. *Peroneus tertius.*—This, which is in fact a mere slip of the extensor digitorum communis, and is situated on its fibular side, is so closely connected with it at its origin that it can with difficulty be separated. It *arises* from the lower third of the fibula, being attached to the anterior border and inner surface of the bone; also from the interosseous ligament, and from an aponeurosis which connects it on the outer side with the peroneus brevis. It is inserted by a flat tendon into the fibular side of the base of the metatarsal bone of the little toe. Its action is to assist in flexing the foot upon the leg.

It is in contact with the fascia of the leg anteriorly, with the fibula and interosseous ligament posteriorly, with the peroneus brevis on the fibular side, and with the extensor communis on the tibial side. Its tendon passes in the same sheath with that of the common extensor, under the annular ligament.

A very slight effort of the extensor communis and extensor proprius pollicis extends the digital phalanges, and, if their action be continued, they will be made to bend the foot upon the leg. This they are enabled to do by the manner in which their line of direction is altered by the annular ligament of the ankle-joint, as it gives them all the mechanical advantage of a pulley. The tibialis anticus and the peroneus tertius are the direct flexors of the foot on the leg, and if either act separately, it will give a slight inclination towards the corresponding side, and thus the last-named muscle forms one of that important set whose action is, by elevating the outer side of the foot, to throw the weight of the body on the inner side.* In the erect position these muscles take their fixed point below, and, by drawing on the bones of the leg, keep them perpendicular on the foot.

The external muscles of the leg are two, the peroneus longus and brevis. They occupy the whole length of the outer side of the fibula, and are placed between the extensors and flexors.

1. *Peroneus longus* is a long powerful muscle, *arising* from a small portion of the fibular side of the head of the tibia, from the upper third of the outer side of the fibula, and from the fascia of the leg and its intermuscular processes. Proceeding obliquely downwards, the fibres are attached to a strong tendon, which passes, in contact with the peroneus brevis, along a groove at the back of the outer malleolus, enclosed in a synovial sheath. The tendon then passes through a deep sulcus in the cuboid bone, behind the base of the metatarsal bone of the little toe, winding obliquely across the sole of the foot, covered by the muscles of this part, till it is *inserted* into the internal cuneiform bone and base of the metatarsal bone of the great toe. In the tendon opposite the cuboid bone, is usually found a sesamoid bone. A bursal sheath encloses it in its passage across the foot. The *action* of this important muscle is to assist in extending the foot upon the leg, but principally to elevate the outer side of the foot, and thus regulate the bearing of the leg so as to throw the principal part of the weight upon the great toe.†

This muscle is in contact on its outer side with the fascia of the leg. Indeed this aponeurosis almost invests it, dipping between it and the flexor behind and extensors before. The peroneus is in contact with the fibula on its inner side above, lower down it rests upon the peroneus brevis. When passing across the foot it lies close to the bones, and consequently is covered by all the muscles of the sole.

2. *Peroneus brevis* is situated at the outer side of the leg, but lower down as to its attachments than the preceding muscle. It *arises* fleshy from the lower half of the outer side of the fibula to near the outer malleolus. It sends off a roundish strong tendon, which passes in the same groove behind the outer malleolus, and in the same synovial sheath as the preceding muscle, but after passing the malleolus it has a sheath proper to itself. It is inserted into the base of the metatarsal bone of the little toe. Connected on its outer side to the peroneus longus, on the inner side to the fibula, anteriorly to the common extensor and peroneus tertius, and posteriorly to the flexor longus pollicis.

The action of these two muscles is peculiar. By the change in their direction, after turning behind the outer ankle, they are enabled to draw the foot back, and so extend it on the leg.

The penoneus tertius is on the contrary a flexor; it lies before the fibula, and combines in this action with the tibialis anticus to assist the flexor. When, however, the three peronei act together, and without the other flexors, their combined action is to evert the sole of the foot, and thus counterbalance the effect of the feebleness of the outer side of the foot by transferring the superincumbent weight to the inner side. This action is particularly exemplified in skaiting, but it is essential to every movement of ordinary progression. (See article FOOT, MUSCLES OF.) When the foot is the fixed point, the peronei act by keeping the fibula and the whole leg steady, and thus, as in the act of standing on one foot, counteracting the tendency of the body to fall inwards.

The posterior region of the leg comprises seven muscles, six of which are acting on the foot and toes, and one is proper to the knee-joint. We shall examine them as they are met with in dissection, and shall therefore describe them as forming two layers, superficial and deep. The first contains three muscles: 1. gastrocnemius; 2. soleus; 3. plantaris.

1. *Gastrocnemius.*—This is situated immediately under the aponeurosis, and is a powerful muscle, broad and flat anteriorly, and convex posteriorly, and forming the greater part of what is called the calf. It *arises* by two distinct heads from the back and upper part of the two condyles of the femur, of which the inner is the longer, and somewhat larger. These heads have between them a broad sulcus, which forms the lower part of the popliteal space. They unite a little below the knee-joint, in a middle tendinous line, and below the middle of the tibia send off a flat tendon which unites with the tendon of the soleus, a little above the ankle.

The posterior surface is covered by the fascia of the leg; anteriorly it rests upon the popliteus, soleus, and plantaris, and popliteal vessels. When its heads pass over the condyles of the femur, they are guarded by synovial bursæ.

2. *Soleus.*— This is the second portion of that great muscle of the leg which has been

* For further observations upon the action of the peronei muscles, see article FOOT, MUSCLES OF.

† See also Quain's Manual of Anatomy.

named by Meckel the *triceps suræ*. It is seen immediately on raising the last muscle. It arises from two distinct situations; first, from the upper and back part of the head of the fibula, and from the posterior surface and outer edge of that bone for some way down. Second, from the oblique ridge on the posterior surface of the tibia, just below the popliteus, and from the inner edge of that bone during the middle third of its length. From these two attachments the muscle almost immediately forms a thick fleshy belly, which descends lower than the gastrocnemius before it sends off its tendon. This, which is flat and strong, soon unites to the tendon of the gastrocnemius to form the tendo Achillis, and is then passing to be *inserted* into the upper and back part of the projecting portion of the os calcis. At its insertion there is a small bursa between the upper part of the bone and the tendon.

The soleus is in contact with the gastrocnemius posteriorly; below its fleshy fibres appear on each side of the tendon of that muscle. Between its two origins the posterior tibial vessels and nerve are passing, defended from pressure by the tendinous expansion which is on the under side of the muscle, and which spreads across from tibia to fibula. This muscle is also in contact with the plantaris, the tendon of which crosses it obliquely from without to within. In front it rests upon the deep layer of muscles and upon the posterior tibial vessels.

The tendo Achillis is the thickest and strongest tendon in the body; it tapers downwards nearly to the heel, and before its attachment expands again a little. It lies immediately under the skin, and between it and the bones is a considerable layer of cellular tissue containing fat.

The action of the two last described muscles is to elevate the os calcis, and thereby to lift up the whole body. When this is done on one foot in the act of progression, the other is capable of being carried forward unimpeded by the irregularities of the surface. When the foot is the fixed point, the soleus by acting on the tibia and fibula fixes the leg, while the gastrocnemius fixes the femur, or by acting further, draws it backward so as to bend the knee and lower the body.

3. *Plantaris.*—This little muscle is entirely covered by the outer head of the gastrocnemius. It *arises* from the upper part of the external condyle of the femur, and from the posterior ligament of the knee-joint. Its muscular structure is only about two inches in length, and it sends its long slender tendon downwards and inwards, between the two great muscles of the calf, emerging from between them just where their two tendons unite; it then passes down in contact with the edge of the tendo Achillis, to be *inserted* into the heel at the inner side of that tendon.

The action of the plantaris is to assist the great extensors of the foot, and to draw upon the capsule of the knee-joint, so as to prevent any ill effects upon that ligament from the motions of the knee-joint. It is occasionally deficient.

The deep layer of muscles consists of four: 1. popliteus; 2. flexor longus digitorum; 3. flexor longus pollicis; 4. tibialis posticus. They lie in close contact with the bones, and the last three of them are covered by the deep fascia of the leg.

This membrane is a thin expansion, dense in structure, connected on each side with the borders of the bones, and towards the ankles with the sheaths of the tendons; and if traced along the interval between the inner ankle and the heel, it will be found to cover the vessels and to terminate at the internal annular ligament. Immediately underneath it we find the deep layer of muscles now under consideration.

1. *Popliteus* is situated below and behind the knee-joint, is flat and somewhat triangular, being broader below than above. *Arises* within the capsular ligament of the knee-joint, by a round tendon, from the under and back part of the outer condyle of the femur; adheres to the posterior and outer surface of the external semilunar cartilage; perforates the back part of the capsular ligament, and forms a fleshy belly which runs obliquely downwards and inwards. It is covered by a thin tendinous fascia from the tendon of the semi-membranosus; *inserted* broad, thin, and fleshy into an oblique ridge on the posterior surface of the tibia, a little below its head, and into the triangular space above that ridge. *Action*, to bend the knee-joint, and when bent, to roll it so as to turn the toes inwards.

2. *Flexor longus digitorum* is thin and pointed at its commencement, but gradually increases, and then diminishes again as its fibres end in a tendon. *Arises* fleshy from the posterior flattened surface of the tibia, between its internal and external angles, below the attachment of the soleus, and continues to arise from the bone to within two or three inches of the ankle. The fibres run obliquely into a tendon, which is situated on the posterior edge of the muscle. This tendon runs in a groove of the tibia, behind the inner ankle, and then passing obliquely forwards into the sole of the foot, receives in its passage a strong slip from the tendon of the flexor longus pollicis. It then divides into four tendons, which pass through the slits in the tendons of the flexor brevis digitorum, and as they run along the under surface of the toes they are bound down by strong fibrous sheaths, within which there are also little accessory ligaments assisting in fixing them. They are *inserted* into the bases of the extreme phalanges of the four lesser toes. The action of this muscle is to flex all the four smaller toes, and to assist in elevating the foot upon the toes.

Previously to its division, the tendon of the flexor longus gives insertion to an accessory muscle of considerable power (*flexor accessorius*), which connects it to the calcaneum, and materially modifies the direction of its action upon the toes. Close to the point of division, the tendons give origin to four small muscles (lumbricales), which may also be considered as accessories to the flexor longus.

When passing behind the inner malleolus, this tendon is in contact with that of the tibialis posticus, which lies close to the bone. They are inclosed in separate sheaths of synovial membrane. In the leg this muscle is bound down by the deep fascia, and covered partly by the posterior tibial vessels which separate it from the soleus; its anterior surface rests against the tibia, and overlaps the tibialis posticus muscle; in the foot, its tendon lies between those of the flexor longus pollicis which are above it, and the flexor brevis digitorum which lies beneath it.

3. *Flexor longus pollicis* is shorter but stronger than the former muscle. It is situated the outermost of the three deep muscles of the leg, in contact with the fibula. It *arises* tendinous and fleshy from the lower half of the posterior surface and outer edge of the fibula, with the exception of the undermost portion. The fleshy fibres terminate in a tendon which passes behind the inner ankle, through a groove in the tibia; next through a groove in the astragalus; crosses in the sole of the foot the tendon of the flexor longus digitorum, to which it gives a slip of tendon; passes between the two heads of the flexor brevis pollicis, and then runs in a sheath of tendinous structure which binds it to the under surface of the phalanx, and is *inserted* into the base of the last phalanx of the great toe. The relations of this muscle in the leg are, posteriorly it is covered by the deep fascia, which separates it from the soleus; anteriorly it is in contact with the fibula, and overlaps the tibialis posticus muscle and the peroneal artery. Its connections in the foot have been explained above. The action of the flexor longus pollicis is not confined to the great toe; by means of the slip of tendon, which it gives to the flexor longus digitorum, it acts also upon all the toes, and secondarily upon the foot itself, assisting powerfully in the elevation of the heel in progression. But the mode of action of this muscle, and its complicated relations with the other muscles of the foot, are too curious to be passed over with a slight examination; in fact, we think it may clearly be shewn that there is here one of the most curious and beautiful arrangements and successions of muscular action to be met with in the whole system. We have elsewhere shewn that, from the peculiar form of the foot, the action of the peroneus longus is essential to transmit the burden of progression from the weaker to the stronger side of the foot. (See article Foot, muscles of.) Let us now follow on the progress of the foot in the act of walking, and we shall readily perceive the succession of action of its different parts, and the functions which each muscle performs. It is evident that the smaller toes being shorter than the large one, and nearer to the heel, they will, in the act of elevating the heel and propelling forward the body, come to their bearing on the ground somewhat before the great toe, their action being, in fact, by the breadth of base which they give to steady the onward progress of the body, and to deliver over accurately and securely the weight to the great toe, the main organ of propulsion of the body. In order to accomplish this to the best effect, it is necessary that the succession of actions should be accurate and complete, and that the muscles of the smaller toes should exert themselves before that of the great toe. To this end the flexor longus pollicis gives a slip to the flexor of the toes, and by the commencement of its action, which merely firmly plants the great toe against the ground, rouses the muscles of the other toes, assisting them to complete their part of the process, while its own labour continues and is at its height when theirs is necessarily accomplished and at an end. Thus, by a beautiful combination and series of actions, the powerful effort of the great extensors of the foot is controlled and guided to its proper end, first by the peronei, next by the flexors of the smaller toes, assisted by the long flexor of the great toe; and the body propelled onwards and balanced on this toe, the action is completed by the further effort of this one powerful muscle. The economy of muscular power is here not less striking than the combination of action, for the flexor longus pollicis being inserted into the last phalanx of the great toe, its own proper action is not called for till after the muscles of the other toes have performed their part; this muscle, therefore, considerably the most powerful of all this deep layer, were it not for the simple expedient of the slip of communication to the other flexors, would be comparatively useless until the last moment of the propulsion onwards of the body. But now it lends its powerful assistance to the weaker muscles previous to its own peculiar effort, and when all its power is called for, the collateral demand has ceased.

4. *Tibialis posticus* is situated on the back of the leg between the last-named muscles. It *arises* fleshy from the posterior surface both of the tibia and fibula, immediately below the upper articulations of these bones with each other. Between the two portions of this attachment is an angular opening through which the anterior tibial vessels are transmitted. The muscle also arises from the whole interosseous ligament; from the angles of the bones to which that ligament is attached, and from two-thirds of the flat posterior surface of the fibula. The fibres run obliquely towards a round tendon, which passes behind the inner ankle, through a groove in the tibia. It is here situated close to the bone enclosed in a separate synovial sheath. It is *inserted* into the tubercle on the plantar surface of the os naviculare, sending tendinous filaments to most of the other bones of the tarsus, and to the metatarsal bones of the second and middle toes. This muscle is covered at the lower part of its origin by the flexor longus digitorum and flexor longus pollicis, and cannot be seen till those muscles are separated. But superiorly it is covered by the soleus only, and here the posterior tibial vessels rest upon it. Its anterior surface is in contact with the interosseous liga-

ment, the tibia and fibula. Its tendon runs close to the inner ankle and tarsal bones, and where it slides under the astragalus, is thickened by a cartilaginous or bony deposit within its fibres, analogous in force and use to the sesamoid bones in other situations. Its action is to extend the foot upon the leg, and to turn the sole of the foot inwards.

(A. T. S. Dodd.)

LIFE.—Few abstract terms have been employed in a greater variety of significations, or more frequently without any definite meaning at all, than the one now to be considered. And there is none regarding which it is more essential to possess correct ideas, in order to attain the fundamental truths of physiological science. The prevalence of what we deem very erroneous notions on this subject, will oblige us to follow a different plan in its treatment, from that which we should have adopted if our duty had been merely to give an exposition of the present state of our knowledge respecting it. We shall commence by offering a short statement of our own views, in order that we may, in the brief historical summary which it will be proper to include in this article, more concisely indicate what we regard as the errors and inconsistencies of the principal theories which have obtained credit at various times. We shall subsequently consider more in detail some of the questions which require fuller discussion.

I. General views.—We shall define Life to be *the state of action peculiar to an organised body or organism.* This state commences with the first production of the germ; it is manifested in the phenomena of growth and reproduction; and it terminates in the death of the organised structure, when its component parts are disintegrated, more or less completely, by the operation of the common laws of matter. This definition differs but little from that given in many physiological works—" Life is the sum of the actions of an organised being;" and we apprehend that we are more in accordance with the common usage of the term, in employing it to designate rather the *state* or *condition* of the being exhibiting those actions, than the actions themselves. In this sense alone it is properly contrary to *Death*, the condition of an organised body in which not only have its peculiar actions ceased, but its distinguishing properties been abolished (see Death); and it is then also contradistinguished from *dormant vitality*, a state frequently observed, in which living actions are suspended, but the vital properties of the organism retained, so as to be capable of again exhibiting them when the requisite conditions are supplied.

Life or vital activity, then, manifests itself to us in a great variety of ways,—in all those phenomena, in short, which it is the province of the physiologist to consider. The changes exhibited by any one living being, in its normal condition at least, have one manifest tendency, the preservation of its existence as a perfect structure; by these it is enabled to counteract the ever-operating influence of chemical and physical laws, and to resist, to a greater or less extent, the injurious effects of external agencies. The first inquiry, then, which we have to make, in the inductive study of physiology, is into the *conditions* of these phenomena; and as in this process we follow precisely the same track as that over which the physical philosopher has already passed, we may advantageously avail ourselves of his guidance in it.

In seeking to establish the laws by which the universe is governed, or, in other words, to obtain general expressions of the conditions under which its changes take place, the enquirer first collects, by observation or experiment,* a sufficient number of instances having an obvious relation to one another, with the view of determining the circumstances common to all. The facility with which this process is performed will obviously depend upon the simplicity of the phenomena, and the readiness with which they admit of comparison. Where their antecedents are uniformly the same, they only need to be associated a sufficient number of times, for the mind to be satisfied of the constancy of the relation; and the general law of the effects is easily deduced. Thus, the law of gravitation is ascertained by the comparison of a number of corresponding but not identical phenomena; and the numerical ratio is established which governs the attracting force. To extend the application of this law, however, to phenomena that seemed beyond its pale, required the almost superhuman genius of a Newton; but the idea, once conceived, was easily carried out when the requisite data were attained. But what is the nature of the *law* of which we have just spoken as regulating the attractive force? It is simply an expression of the *property* with which the Creator has endowed all forms of matter, that its masses shall attract or tend to approach each other in a degree which varies in a certain ratio to their mass and distance. This property, it must be recollected, is *only* assumed to exist, as the common cause of the actions constantly occurring under our notice. If none of these actions were witnessed by man,—if, for example, but one mass of matter existed in the universe,—it might be endowed with this and every other property which we are accustomed to regard as essential to matter; and yet, from gravitation never being called into action, the mind would remain ignorant of the attribute.

Such a common cause, the conditions of whose action are so simple and uniform that we can account for, and even predict, by a process of deduction, all the phenomena which it can operate to produce, may be regarded for a time as an *ultimate fact*. It may still, however, be capable of union with other facts of a

* For the proper distinction between these modes of research, and their respective applications to physiology, see Brit. and For. Med. Review, April 1838, pp. 320 *et seq*.

similar order, under a still more comprehensive expression.* But it is not in every department of science that the same facility in the attainment of general laws exists. Where the phenomena are of such a complex nature that the operation of the real cause is, as it were, masked by the influence of concurrent conditions, or where (as often happens in physiology) the effects of the same apparent cause are totally different according to the instruments through which it operates, it is obvious that there will be great difficulty in the first stage of the inductive process—that of the classification of phenomena,—so great, indeed, that it may be regarded as one of the principal obstacles to the advancement of those branches of science in which it presents itself. Of all the branches of physical science, that of meteorology is the most obscure and apparently uncertain, and bears most resemblance to physiology. The changes which it concerns are daily and hourly occurring under our observation; and the general laws which govern them are tolerably well ascertained; yet the mode in which their actions are combined is so peculiar, as hitherto to have baffled the most persevering and penetrating enquirers, in their attempts to explain or predict their operation. But no one thence feels justified in assuming the existence of any new or unknown cause, capable of controlling or subverting the influence of the rest; and such a proceeding would not be justifiable, until all their *possible* modes of action have been ascertained and put aside, leaving certain *residual* phenomena not otherwise to be accounted for.

The peculiar difficulties which beset the investigation of the laws of *vital action* have greatly retarded our acquaintance with them, and have even led to the belief that the inductive process is not applicable to them. These difficulties have arisen, in the first place, from the obstacles in the way of the collection of phenomena; secondly, from the peculiarly complex nature of these phenomena; and, thirdly, from the vague hypotheses which have prevented them from being classed as simple facts on which generalisations are to be erected, or effects whose sources are to be ascertained, but which have clothed them in the delusive aspect of laws or causes. Until, therefore, the principles of philosophical induction are thoroughly understood, the peculiar combinations in which vital phenomena present themselves to our notice, their apparent dissimilarity from the changes which we witness in the world around, and their obvious adaptation to particular ends, might lead us astray into the labyrinth of unprofitable speculation with regard to the presiding agencies by which they are governed; and the retrospective view which we shall presently take will afford many examples of this error, even in recent times, and will in fact show that the legitimate objects of investigation, and the true mode of pursuing them, are only now beginning to be understood.

* Such would seem to be the tendency of certain recent speculations in regard to gravitation, molecular and electrical attraction, and chemical affinity.

When we observe the circumstances under which vital actions occur, we perceive that at least two conditions are required for their production. The first is a structure in that peculiar state which is termed *organised* (see ORGANISATION); the second is a *stimulus* of some kind fitted to act upon it. Now this is no more than what we observe in the world around, where every action involves two conditions of a corresponding character. When water is changed into steam, for example, it is by the *stimulus* of heat. When a stone falls to the ground, it is by the attraction which the mass of the earth exercises over its own. The difference consists in the *peculiarity* of the actions exhibited by living beings, which are not identical with those elsewhere presented to us, and which we cannot imitate by any physical or chemical operations. Whilst the mechanical philosopher, then, refers to the *property* of gravitation as the cause of the effect just mentioned, the physiologist refers to the capability of exhibiting vital actions, when excited by certain stimuli, as the *property* of the tissue which manifests them. Thus, when he witnesses the contraction of a muscle, under the stimulus of innervation or of galvanism, &c. he regards the effect as due to a property of *contractility* inherent in the muscle, and standing in precisely the same relation to its organic structure, as gravity to matter in general. So far, however, the advance in our inquiry is more apparent than real; since it may fairly be said that, to speak of contractility as the character of a body exhibiting contractions, is merely a change in words without absolute gain. But, having done this, we are led to inquire the conditions under which this contractility operates; and to analyse a number of phenomena apparently dissimilar, so as to attain the general law of its action. In this manner we proceed in regard to other classes of phenomena; and we shall thus acquire (when our data are sufficiently precise and extensive) a knowledge of the properties of all the tissues or organised structures which compose the living body, and of the phenomena which their single or combined operation will produce, under the influence of their respective stimuli.

But the physiologist will not stop here. He will seek to inquire to what these properties are due, which are so different from anything exhibited by the same matter before it had become a part of the organised system. And, if he consider the matter in all its bearings, with a total dismissal of prejudice, he will be unable, we think, to arrive at any other conclusion than that they are due to the act of organisation, which, in combining the inorganic elements into new compounds, and giving them a peculiar structure, calls out or developes in them properties which had previously existed in a dormant state, but required these circumstances for their manifestation. To this question, however, we shall presently return, when considering other views which have been entertained respecting it. We shall now take a retrospective glance at the

II. History of opinions.—In the earlier ages of the world, before the true method of philosophising on any subject was understood, it was considered as a sufficient explanation of any phenomenon to apply to it some abstract term, expressing a vague idea of a property inherent in the body which exhibited it, without attempting to ascertain the conditions of its operation.* Thus, all the phenomena of the movements of the heavenly bodies were attributed to the agency of a "principle of motion," the laws of which were scarcely even sought for. In like manner, the simple optical fact—that, when the sun's light passes through a hole, the bright image, if formed at a considerable distance from it, is always round, instead of imitating the figure of the aperture,—was attributed by Aristotle to the "circular nature" of the sun's light; whilst the mere consideration that the rays of light travel in straight lines, would, if properly applied, have explained this phenomenon, not only as regards the sun, but in the case of any other round luminous body placed at a sufficient distance. It is not wonderful, then, that the still more intricate nature of the phenomena exhibited by living beings, the obvious tendency of those presented by each individual towards the same end, and the seductive simplicity of the hypothesis, should have induced the philosophers of that age to regard all vital actions as the immediate results of one common cause; but that such a belief should have maintained its ground, with but little alteration, to the present day, can only be regarded as a proof of the lamentable deficiency in truly philosophical views among the cultivators of physiology.

To the supposed *cause* of vital phenomena the term *Life* was applied by the older philosophers, who regarded it as a distinct entity or substance, material or immaterial, residing in certain forms of matter; and the cause, both of their organisation, and of the peculiar actions exhibited by them.* Every sect had its own notion of the origin and nature of this entity; some regarding it as a kind of fire; others as a kind of air, ether, or spirit; and others, again, merely as a kind of water. The fable of Prometheus embodies this doctrine in a mythological form, the artist being described as vivifying his clay statues by fire stolen from the chariot of the sun. Whatever was the idea entertained as to the character of this agent, all regarded it as universally pervading the world, and as actuating all its operations in the capacity of a life or soul; whilst a special division of it—a *divinæ particula auræ*—regulated the concerns of each individual organism. The opinions of Aristotle on this subject are very interesting, as presenting evidence of the tendency of his powerful mind to elevate itself above the level of his age, and as showing how completely even *he* was bound down by the prevalent tendency to hypothetical speculation, which seemed to offer so easy a solution to all the mysteries of Nature. "In considering what holds the fabric of the universe together, and forms out of the discordant elements a harmonious whole, he infers from analogy that it must be something similar in kind to that which forms and holds together an organised body, namely, a principle of life; and that this principle, from the appearance of order and design displayed in the universe, must also have intelligence." "Besides this supreme animating principle (Φυσις), the author and preserver of all, there are many others which, by delegated powers, organise the bodies of animals and plants, so that all organised bodies whatever are to be considered as constructed by and constructed for their animating principles, which, like the great animating principle, from being invisible to mortal eyes, indicate their existence, their energies, and their species, only through the medium of the structures which they form. Now, of these structures they are not only the efficient causes but, in his opinion, the formal and the final; the causes of their motions, growth, and nutrition; the causes which give them a character and form; the causes on whose account they exist; and even the causes of their being afterwards liable to corruption, as nothing is corrupted but what has been nourished, and has some time or other partaken of life. But, besides being causes of organised structures in these different senses, they are subordinate to a higher power, which prescribes their operations, not merely with reference to their separate and individual plans, but with a reference at the same time to that general and comprehensive

* This mode of philosophising has been very happily ridiculed by Fontenelle. "Let us imagine," he says, "all the sages collected at an opera—the Pythagorases, Platos, Aristotles, and all those great names which now-a-days make such a noise in our ears—let us suppose that they see the flight of Phaeton as he is represented carried off by the Winds; that they cannot perceive the cords to which he is attached, and that they are quite ignorant of everything behind the scenes. It is a secret virtue, says one of them, that carries off Phaeton.—Phaeton, says another, is composed of certain numbers which cause him to ascend. A third says, Phaeton has a certain affection for the top of the stage; he does not feel at his ease when he is not there.—Phaeton, says a fourth, is not formed to fly; but he likes better to fly than to leave the stage empty; and a hundred other absurdities of this kind, that would have ruined the reputation of antiquity, if the reputation of antiquity for wisdom could have been ruined. At last come Descartes and some other moderns, who say, Phaeton ascends because he is drawn by cords, and because a weight more heavy than he is descending as a counterpoise. Thus to see nature as it really is, is to see the back of the stage at the opera."—Quoted in Brown's Lectures on Mental Philosophy, Lect. v.

* The term Ψυχη was applied by the Grecian philosophers to designate this animating principle, which included, with what is *now* known as the vital principle, the sensory and intellectual faculties. To the series of vital actions which, by many modern physiologists, is spoken of as Life, the term Ζωη was given by the Greeks.

plan on which the universe itself is constructed. It is under the influence of such a power that every particular species of soul regularly constructs a system of organs adapted to its functions; and every species of soul appears uniformly to have its own species of body."* Now it is a little singular that, whilst the tendency of modern philosophy has been to explode the idea of any secondary existence acting beneath the Creator on the constitution and actions of the universe, but to refer all its phenomena to the continued operation of the laws which He first impressed on matter, physiologists, neglecting the obvious analogy between the actions of the universe and those of any single organised being (the Macrocosm and Microcosm) pointed out by Aristotle, should have retained, with but little modification, his opinion regarding the second; and should still attribute the phenomena of life to a secondary agency existing in each being and modifying the ordinary laws of matter to its purposes. This subject, however, we shall dismiss for the present, to return to it hereafter.

The mode of explaining vital phenomena which has been adduced as an example of early speculation on the subject, appears to have resulted from two tendencies that may be observed to characterise the unenlightened mind both in past ages, and at the present time. The first is that which may be considered as natural to man in the infancy of philosophy,—to regard all matter, at least the grosser forms of it, as essentially inert, and therefore to attribute all spontaneous motion to a union of the thing moved with some substantial moving cause. Now, although modern science has given a more correct explanation of the causes of motion in the inorganic world, and has shown that, so far from being inert, every particle of matter is capable of exhibiting actions of various kinds when placed in certain relations to others,—the superficial enquirer still regards matter as inert *quoad* vital actions, and is unwilling to attribute them to any possible operation of its properties. And in this mode of reasoning he would seem borne out by the peculiar history of organised beings,—the phenomena of their origin, growth, decline, dissolution, and decay,—the contemplation of which, with the desire of accounting for them, occasions the second tendency to which we have alluded; that, namely, to infer from this history the existence of an unknown *something*, which during the living state preserves the integrity of the body, and the loss of which occasions the disintegration of the fabric. Thus it has happened that the doctrine of the animating principle has retained its hold over the public mind from the earliest ages of the world to the present day; and the vestiges of the opinions of the early Greek philosophers may be traced in the expressions, vital spark, vital spirit, breath of life, and others which are still prevalent.

* Barclay on Life and Organisation, pp. 429-433.

The chief modification which these doctrines have undergone, in their transit to modern physiologists, has been the separation of the vital principle—the entity which is supposed to effect the organisation of the body, and to employ that organism as the instrument of its operations—from the soul or mental principle, which is concerned in a series of actions entirely distinct. It is somewhat singular, however, that even Aristotle regarded the νους or reasoning faculties as separable from the remainder of the Ψυχη, and as capable of existing independently of the body; and a subdivision of this kind was adopted by the Roman philosophers, who designated the vital and sensitive principles by the term *Anima*, whilst to the rational they applied the name of *Animus*. We shall not follow these doctrines through all the modifications which resulted from the unfathomable profundity of some systems of philosophy, and the pretending shallowness of others; but shall proceed at once to the more modern opinions, which are either openly professed at the present time, or lurk in the unillumined corners in which the heterogeneous relics of former systems find a hiding place, whose darkness is congenial to their disunited formlessness.

The ancient doctrine of the identity of the vital with the mental principle was revived by Stahl in a somewhat altered form. This philosopher maintained that the *rational soul* is the primum movens of organisation; that it is the ultimate and sole cause of organic activity; and that by its operation, according to certain fixed laws, it preserves the body from decay and cures the effects of disease. Still, however, a distinction was drawn by him between the acts of the *animus* and the *anima*, which was not observed by his followers, who have regarded him as wishing to identify them. He looked upon them as the common effects of one principle; and his great error was in supposing that any analogy or parallelism existed between them. Now it is necessary to bear this doctrine constantly in mind when reading the works of many of the physiologists of the last century, otherwise their meaning will be greatly misunderstood. In the writings of Whytt, for example, we constantly find actions referred to the *soul* as their cause, when it is perfectly evident that the author did not mean that the *mind* (as it is now termed) was at all concerned in them. This was the case with his whole class of vital and involuntary motions, to the production of which, he expressly states, *consciousness* is not always necessary. Although there are few if any philosophers who would avow such a doctrine as that of Stahl at the present time, we trace its effects very evidently exerted upon popular opinion. We have known it maintained by many well-informed persons, that the phenomena of life and mind are obviously so closely connected, that, to refer one class to the operation of the properties of matter without an independent controlling entity,—in other words, to set aside the doctrine of a vital principle,—necessarily implies the relinquishment of the idea of mind as a distinct existence. Nothing, however, can be more absurd than such a dogma. The two classes of phenomena are not connected otherwise than by a very remote analogy. All the phenomena of Life (putting aside, of course, those psychical changes with which we are contrasting them) concern matter only, and consist in its actions and reactions, and there is nothing in them related to feeling or consciousness; it is but reasonable, then, to refer them to the laws of matter if we can do so. But the phenomena of mind are universally allowed to be of a very different character; there is nothing tangible or material about them; and, whether we regard them as causes or results of material changes, our reasons must have a very different basis than the existence or non-existence of a vital principle. On this point all the most intelligent of modern writers are fully agreed.*

The doctrine of "the vital principle," which is at present very commonly received under some form or other, may be regarded as having been first put forth in a distinct form by Barthez, who invented this term to signify something distinct from either mind or body, but nevertheless capable of existing by itself. The *vis medicatrix naturæ*, which figures so prominently in the theories of Hoffmann and Cullen, is nothing more than the same hypothetical agent under a different name; for by this term was denoted a " sort of in-dwelling guardian of the body," which " presides over its functions in the state of health; and, when any accidental cause of disturbance has given rise to a temporary disorder in the system, exerts itself to the best of its ability, with a sort of instinctive effort, often well directed, though sometimes liable to mistake, to restore the healthful and regular condition."† No one can have observed the phenomena of Life in morbid conditions of the body without witnessing examples of the *tendency* to reparation in the various parts which have suffered from the ravages of disease or injury; but this tendency results, like their ordinary operations, from their original constitution as parts of an organised system, and not from any independent agent whose existence can be demonstrated; so that if the common phrase, " the healing power of Nature," be employed at all, it should only be used as a general term for the expression of this tendency. Precisely the same may be said of the " Nisus Formativus," or *Bildungstrieb* of Blumenbach. If it be employed merely as a general expression of phenomena evidently directed by their unknown cause or causes towards the same end, it is unobjectionable; but care must be taken lest it be supposed that something has been gained by such a generalisation, which, in fact, merely refers to the *final cause* and not to the *efficient* cause, and does not, therefore, carry us forward one step in the inquiry into the latter. If, on the other hand, it is intended thus to designate an agent whose operations produce these phenomena, it cannot be distinguished in any way from that commonly spoken of as the vital principle. Of a similar character would seem to be the "organic agent" of Dr. Prout, the "organic force" of Müller and other German physiologists. If by them are intended any *entities* separate from matter, or any forces distinct from those which the action of its properties creates, they evidently come under the same category.*

We arrive, then, at last at the doctrine of the vital principle, which, since the time of Hunter, has prevailed in Britain, especially amongst his disciples, until a comparatively recent period, when its unphilosophical character, its inability to explain the phenomena of Life, and the absence of any valid evidence for such an hypothesis, have been made apparent. It is not easy to discover, however, from his writings, what were the precise opinions of Hunter upon this topic; for the inquirer is constantly perplexed by the peculiar vagueness of his expressions, which, if taken in a rigid sense, would indicate ideas quite opposed to one another. Thus, we find him at one time speaking of the brain as itself the *materia vitæ* in a concentrated state, and speculating that " something similar to the materials of the brain is diffused through the body, and even contained in the blood." But he elsewhere intimates his opinion that the principle of life is independent of organisation, a something superadded to the organised structure, as magnetism to iron, or electricity to various substances with which it may be connected. This view was warmly espoused by Mr. Abernethy; so warmly, indeed, that he almost transforms the *analogy* into *identity*, maintaining that " if the vital principle of Mr. Hunter be not

* Thus Mr. Abernethy, in his Exposition of Hunter's Theory of Life, contended against confounding perception and intelligence with mere vitality. Dr. Prichard remarks (Review of the Doctrine of a Vital Principle, p. 71,) that the conscious principle or mind and the vital principle, " supposing for a moment that both really exist, are entirely distinct in their nature and attributes." And Dr. Alison's authority fully coincides with those already quoted. " Whatever notion we may entertain respecting the existence of a vital principle, it has no connexion with our notion respecting the existence of mind." (Outlines of Physiology, p. 3.) These three physiologists may be regarded as fairly representing three different classes of opinions regarding the vital principle; the first being a zealous partizan of its claim to be considered a distinct entity, the second as zealous an opponent of the doctrine, and the third taking an intermediate position.

† Prichard, op. cit. p. 17.

* Such expressions, says Rudolphi, (Translation by How, p. 216,) may be approved of " when it is wished briefly to mention the unknown cause of life; but it is extremely objectionable to presume that they have thereby explained anything. Authors generally commence at first with the modest declaration that they mean, by the word *vital power*, no more than the unknown origin of life; but this mask of modesty is presently thrown aside, and they proceed as if the thing had been quite clearly proved. It is now become a *something* which is imparted to the body in a certain quantum; and they talk of increased and diminished, exalted and fallen vital power, &c., and thus they have a *Deus ex machinâ* which must help them through all obstacles. In such a case was Brown with his Excitability."

electricity, at least we have reason to believe it is of a similar nature, and has the power of regulating electrical operations."

We shall now inquire into the precise import attached to the term by those who continue to employ it. It has been well remarked by Mr. Mayo that the word *principle*, "characteristic of a less advanced state of science, has been generally employed (as the final letters of the alphabet are used by algebraists) to denote an unknown element, which, when thus expressed, is more conveniently analysed." Thus, it has been customary to speak of the principle of gravity, of electricity, or of magnetism, as the unknown causes of certain phenomena, whilst these are imperfectly comprehended. In so far, however, as the laws of these phenomena are understood, they terminate in referring all the results to simple properties of matter, from which they may be deduced by demonstrative reasoning, just as geometrical theorems from the postulates on which they are founded. But in the science of physiology the term has been employed in a less justifiable sense. It must be admitted on all hands, that the conditions of vital phenomena are not yet determined with sufficient precision to enable us to refer all observed facts, through the medium of general laws, to simple vital properties; and there would be no objection, save the probability of its abuse, to the employment of the term "Vital Principle," like "Nisus formativus" or "Organic Force," as a convenient expression for the sum of the unknown powers which are developed by the action of these properties. But to this limit physiologists have unfortunately not restricted themselves. They have regarded it as a distinct entity endowed with properties of its own, in virtue of which it acts upon matter,—removing its particles from the pale of physical and chemical laws,—transforming them into organised tissues,—endowing these tissues with new properties,—prompting their actions,—preserving their composition in defiance of external influences which would tend to disintegrate them,—and finally quitting them, or being itself worn out with them, so as to leave the framework without its protecting influence, deprived of which it speedily falls to decay.

Of the character of this principle, its expositors leave us very much in the dark. Of all modern writers, Dr. Prout is probably the one who has most plainly expressed himself on it. In his Gulstonian Lectures* he informs us that, "In all cases it must be considered an ultimate principle, endowed by the Creator with a faculty little short of intelligence, by means of which it is enabled to construct such a mechanism, from natural elements, and by the aid of natural agencies, as to render it capable of taking further advantage of their properties, and of making them subservient to its use." The fallacies involved in this supposition have been elsewhere so ably exposed† that we shall not here stop to discuss it; but in our survey of the nature and causes of vital actions, we shall take occasion to inquire whether any such hypothesis is called for, or whether it is not worse than useless by complicating what is otherwise readily explicable on simple and philosophical principles.

* Medical Gazette, vol. viii. p. 261.

† Roberton on Life and Mind, p. 36 et seq.

III. Nature and causes of vital action.

It has been already pointed out that all the changes in the external world are the results of the properties of inorganic matter, called into exercise by the means appropriate to excite or stimulate each to activity; and we may further observe that these means are different for each property. Thus, to develope the dormant property of gravitation in any mass of matter, we should only have to bring it within the sphere of attraction of any other mass. But to develope the dormant electrical property of a loadstone, a mass of iron alone would serve. Every operation in chemistry is founded upon the same principle, each substance acted upon being capable of responding, in a manner peculiar to itself, to the influence of agents brought to bear upon it. Now, however familiar this idea may seem, it has been too much neglected in the investigation of vital phenomena; and notwithstanding that we always find a similarity of action, when the organised structure, on the one hand, and the stimuli which call its properties into activity, on the other, are identical—and a difference in either of these conditions always producing a difference in the result,—physiologists have been in the habit of looking to some other agency for the cause of the variation. It is true that we occasionally meet with instances in which the result is different, without our being able to detect any change in either of the conditions; but, knowing as we do how very slight an alteration in the structure of a tissue or organ will at once destroy or entirely change its vital properties, we cannot wonder that they should undergo important modifications without their sources being perceptible to our present means of research; and, as will hereafter be more fully shown, every extension of our powers of observation renders this doctrine more probable.

When we analyse the mass of phenomena which are presented to us by the vital actions of the organised world, we find that they are susceptible of reduction into distinct classes, by which the study of them is much facilitated. Thus, all living beings introduce into their own structure alimentary materials derived from external sources; and all likewise submit their fluid ingredients to the influence of the element they inhabit, in such a manner that a reciprocal change occurs between them. In this mode we arrive at the notion of the distinct *functions* of living beings, each of which may be regarded (in its simplest form) as a group of phenomena of similar character and referable to the same causes. Thus, the function of respiration, when stripped of all the acts sometimes associated with it, is essentially the same throughout the whole organized world;* and the simplicity of the changes involved in it,

* See Prin. of Gen. and Comp. Phys. ch. ix.

together with the facility with which it may be made the subject of experiment, render our knowlege of its character and conditions nearly complete.

When we have analysed these groups of vital phenomena and satisfied ourselves of the conditions under which they occur, we are brought to the conclusion that for each a particular organ or species of structure is appropriated in the organized system, and that its action is dependent upon the excitation of its properties by agents external to it, just as in the inorganic world. This dependence of life upon external stimuli has been completely overlooked by the advocates of the vital principle; and it is probably to Brown, with all his faults and absurdities, that we owe the first prominent enunciation of the fact. When these stimuli are withdrawn, vital action ceases; though, under favourable conditions, vitality or the vital properties of the organism may be retained. (Sect. VI.)

Every class of organs in the living body may be said to require its particular stimulus for the display of its properties. Thus, regarding the whole structure as a series of *assimilating* organs—capable of converting nutrient materials into structures like their own, and of thus causing them to exhibit vital properties—we may say that the supply of these nutrient materials in a fluid state is the stimulus to their action. Again, to the *excretory* organs the required stimulus is the presence of certain superabundant and therefore injurious elements in the nutritious fluid. To the action of the muscular system the excitement of innervation, or the application of a physical stimulus, is necessary. In all classes of living beings we find these functional changes performed under conditions which are essentially the same; and hence we are enabled to arrive at the laws which regulate each.

These are not the only conditions required, however; for others of a still more general nature are constantly, and therefore imperceptibly, operating. All vital actions, for example, require a certain amount of *heat* for their performance, and the amount varies in different cases. This is no more, however, than what we meet with in the inorganic world; for many chemical and physical operations can only take place within certain limits of temperature, and these sometimes very circumscribed. The presence of *light*, again, is essential to many others, especially in the vegetable kingdom; but this, again, finds its parallel in the inorganic world, many chemical decompositions (which indeed bear a remarkable analogy with the changes which this agent produces in the green parts of plants when exposed to an atmosphere containing carbonic acid) being due to its influence. And although, with regard to *electricity* as a vital stimulus, our absolute knowledge is still less, what we do know leads to the belief that it is an agent of at least as much importance in the vital economy as in the operations of inorganic nature.

There is nothing, then, in the nature or conditions of vital actions considered individually, which need cause us to reason upon them in any other way than we do upon the phenomena of the inorganic world; and it is obviously unphilosophical to *assume* an agency which is not required to account for them. It must be recollected, too, that the *onus probandi* rests with those who make the assumption, and not with those who maintain the analogy in the character of vital phenomena to those of the universe at large. The assumption may be easily shown to be not only useless, but insufficient to explain phenomena without calling to its aid the very principles which have been shown to be themselves competent. Thus, the physiologist who traces the operation of the vital principle in the function of secretion, is compelled to allow that, as by one principle so great a variety of products are eliminated by the various glands from one material, the difference in the results must be due to some difference in the structure of the organs respectively concerned. And it may then be fairly inquired of him, "If the difference in the glandular structure and action is capable of giving rise to so great a variety in the products, with the cooperation of this one vital principle, how can it be proved that this difference in the glandular structure and action may not be capable of giving rise to the same result by itself, and without the aid of any such adjunct at all?"* A similar question might be put with regard to any other class of actions, in which, under the same general conditions, the results are modified by the peculiar characters of the instruments or organs respectively employed; and, as a negative reply must be given equally to all, it may be safely affirmed that no reasoning can deduce the doctrine of a vital principle from the phenomena of life separately considered.

But the advocates of the doctrine rely much upon the peculiar adaptation of the various changes taking place in each being to the purposes of its existence; and assume that this adaptation can only result from the control of a subordinate presiding agent constantly exercised over each. Here, again, we find such a doctrine not only unsupported by, but manifestly inconsistent with, the analogies of nature. No reflecting mind has any doubt that this earth and its inhabitants form a system, of which every part is perfectly adapted to the rest, (so that we might almost call it an *organised* one, if the idea of a particular structure were not involved in the term,) and of which all the actions and changes, however in appearance contrary, have one common tendency—the ultimate happiness of the creatures of Infinite Benevolence. The same may be said of it in regard to its relations with the system of which it forms a part; and probably of that system with regard to the universe in which it is but a speck. So far as we can understand the working of the laws by which that universe is governed, we see them all mutually adapted to the same ends, whether we consider the welfare of the whole system, or of our own comparatively insignificant planet, with

* Prichard on the Vital Principle, p. 100.

its countless living inhabitants. Have we, then, any more reason to assume that a vital principle or organic agent governs the concerns of each of these beings, than to suppose that the Creator has delegated to a subordinate the care of each individual globe? Or is it not more consistent to suppose that upon the elements of *all* He impressed those simple properties, from whose mutual actions, foreseen and provided for in the laws according to which they operate, all the varieties of change which it was His intention to produce, should necessarily result?

By another illustration of a different character we hope to set this point in a still clearer light, and to be able to dismiss the subject without entering upon it as an abstract question. We shall suppose a young physiologist, entirely ignorant of physical science, but educated in implicit faith in the vital principle, witnessing for the first time the action of a steam-engine. Here he would perceive a machine composed of a number of dissimilar parts connected together, and moving by some secret agency which he desires to unveil. We may imagine him trying various experiments upon its functions,—such as shutting off the communication between the boiler and the cylinder, or between the cylinder and the condenser,—or applying cold where heat should be, and kindling a fire under the cold-water cistern. Hence he may arrive at the just conclusion that the actions performed by each part, when the machine was in regular operation, have all a tendency towards one common object—the maintenance of its moving power. He will also perceive that these actions are as dissimilar as the structure of the parts exhibiting them; and he will not escape being surprised that the opposite influences of heat and cold should be essential to their production. Hence he may safely conclude that the whole series of phenomena is due to one presiding agency—a "steam-engine principle,"—by the operation of which upon the material structure, its actions are produced, and made to harmonize with each other, and with their ultimate object. And this conviction would be very much strengthened if he saw the machine endowed (as we may, for illustration, imagine quite possible) with the means of supplying its own wants,—regularly adding fuel to its fire, and cold water to its condensing cistern,—and even repairing for itself the loss it sustains by wear of material. Would such a person, entirely unacquainted with the properties of steam, be acting more unphilosophically in entertaining this notion, than in attributing the actions exhibited by living beings to the operation of a vital principle? We think not. In each case the machine or organism is framed to take advantage of the properties with which the Creator first endowed matter; and the difference is that, while the design of man constructed the first to bring into operation those properties which alone he can control, the design of Omnipotence constructed the second, and adapted it to develope properties of matter, which can only be exercised under the conditions which a living being supplies, and of which man, therefore, cannot avail himself.

We may conclude, then, that if we can refer vital actions to the *properties* of the organs which exhibit them, called into operation by their appropriate stimuli, we do not require any other explanation of their mutual adaptation and dependence than the original design of the Creator. "No agent," it has been well remarked, "can be required to adjust and regulate the actions which ensue from this mutual adaptation, since they are, like all other phenomena in the universe, under the control of laws inseparable from their very existence." But the question next arises, by what means have organised bodies become possessed of these peculiar properties? It is, as we have before remarked, a mere verbal alteration to attribute the vital actions of an organ to its peculiar properties; since we understand by these properties only the *capability* of giving rise to the changes which we witness, and we only know of their existence by the observation of these changes. The real *causes* of the phenomena must be sought for in the events which were concerned in the formation of the structure, and its first endowment with the properties which it exhibits; and this leads us to consider,

IV. The connection between vitality and organisation.—When our enquiry into the laws of Physics terminates in referring any of its phenomena to the action of one of the *universal* properties of matter, we feel satisfied that we can trace the operation of second causes no higher; and that the existence of this property as inseparable from matter, and therefore as essential to our idea of it, is the immediate result of the will of the Creator. But in a great variety of instances we cannot do so; and we observe properties restricted to and inseparable from certain forms of matter, the laws of whose action, however, are as definite as in the first case. Such properties, therefore, form a part of our notion of those particular forms of matter; thus, the magnetic properties of iron, or the energetic attraction which potassium has for oxygen, are characteristics of these substances, which combine with others to distinguish them in our minds from other forms of matter possessing many properties in common with them. But these properties will not be manifested except under peculiar conditions; and according to the rarity of the occurrence of those conditions will be the probability of our remaining ignorant of the property. We are obliged to admit, therefore, that every form of matter with which we are acquainted may have properties of which we know nothing, simply because it has not been placed in the circumstances adapted to call them into activity; since it is only by an *action* of some kind that the mind can become cognisant of their existence. We see, then, that it is very possible that all matter, or at least all those forms of it capable of becoming organised, may be possessed of properties which shall give rise to the actions termed *vital*, when they are placed in certain conditions; and that the mere absence of any manifestation of these, while the substance remains in the condition of inorganic matter, is no proof that they do not appertain to it.

We find nothing, then, in our fundamental ideas of matter, to oppose the doctrine that vital properties are developed in it by the very act of organisation. But we shall consider the question in another point of view. We are constantly witnessing examples of the *total change* effected upon the properties of certain forms of matter by their entrance into new combinations. Thus, how completely different are the properties of a salt from those of the acid and alkali which unite to form it. And we are not obliged to have recourse to chemical union for cases of such a change; since there are examples in which mere mechanical admixture of the particles of different bodies will produce the same. How different, for instance, are the properties of gunpowder from those of any of its ingredients. They are all combustible it is true; but in a manner as unlike it as each other. Does any one think of assigning any other cause to these changes than the act of combination or admixture? Does he seek for it in the operation of a saline property *superadded* to the compound of acid and alkali; or of a combustible *principle* presiding over the combined actions of the nitre, sulphur, and charcoal, and directing them to one common object? If not, why should he adopt a different course in regard to vital properties?

In our investigation of natural phenomena, we *never* observe a substance endowed with new properties, without it has undergone some change in its own condition, of which altered state these properties are the necessary attendants. Unless, therefore, an instance could be produced in which the *same* form of matter shall at one time evince properties of which it is proved to be destitute at another, we have no right to speak of any *property* as *distinct* from the matter which exhibits it, or as capable of being *superadded* to it or subtracted from it. It may be desirable for us to pause here, in order to examine a case in which it has been alleged that such an addition takes place, and which has been used as an analogical argument in support of the doctrine of a vital principle. It has been commonly said that a living body, in assimilating and organising the nutrient matter by which the changes essential to its existence are maintained, superadds or communicates to it by a separate act, those vital properties of which it was itself previously possessed; and there is no more difficulty, it has been argued, in conceiving how vital properties may be communicated to organised matter, than in understanding how magnetic properties may be superinduced upon iron. But the analogy is based upon a false conception of the latter process, which is really conformable in character to those by which gravitation or any other properties of matter are brought into action. For the so-called communication of magnetic properties to iron is nothing more than the production of a change in the conditions of the metal, by which its electric properties are manifested in a manner peculiar to itself, and caused to give rise to magnetic powers. If, then, an analogy exists between the two processes, (which can scarcely be denied,) it leads us to the belief that, just as magnetic powers are developed in iron, when the metallic mass is placed in a condition to manifest them, so the very act of organization developes vital powers in the tissues which it constructs. For no one can assert that there does not exist in every uncombined particle of matter which is capable of being assimilated, the ability to exhibit vital actions when placed in the requisite conditions; in other words, when made a part of a living system by the process of organisation. It is only the complexity of the conditions required to manifest it, which prevents our recognising this capability as a common property of matter, or at least of those forms of it which we know by experience to enter into the composition of organised structures.

Such are the conclusions to which we are led by the general comparison of vital phenomena with those of the external world; and it would be difficult, we might say impossible, to prove that there is anything in the former which removes them from the pale of such reasoning. In fact, it appears to us that observation of them alone would lead to similar inferences. We perceive organisation and vital properties simultaneously communicated to the germ by the structures of its parent; those vital properties confer upon it the means of itself assimilating, and thereby endowing with vitality, the materials supplied by the inorganic world. It is very true that in this germ we cannot perceive a single trace of the future being, the various organs and structures of which are evolved during its development. But these are not evolved in any other way than by the progressive extension and complication of the parts of the original germ. If we witnessed the aggregation of inorganic matter to form a head in one place, a trunk in another, and limbs in a third, and the subsequent union of these, we might be disposed to suspect the existence of some invisible agent which directed and controlled the operation; but we can trace nothing in the real process but the effect of the properties with which the structure of the germ is endowed at the same time and by the same act that it is organised by the parent. Nor is there anything in the subsequent life of the being that opposes such a view; on the contrary, much that confirms it. As long as each tissue retains its normal constitution, renovated by the actions of absorption and deposition by which that constitution is preserved, and surrounded by those concurrent conditions which a living system alone can afford, so long, we have reason to believe, it will retain its vital properties, and no longer. And just as we have no evidence of the existence of vital properties in any other form of matter than that denominated organised, so have we no reason to believe that organised matter can retain its regular constitution, and be subjected to its appropriate stimuli, without exhibiting vital actions. The advance of pathological science renders it every day more probable that derangement in function always results, either from some structural alteration (although this may be of a kind imperceptible to our senses), or from some change in the character of the stimuli by which the properties of the organ are called into action. There is no difficulty, therefore, in accounting on this view for the death of the whole system on the cessation of any one function; since any perturbation in the train of vital actions will not merely disturb the regularity of all, but, if sufficiently serious, will check those nutrient processes on the uninterrupted continuance of which the vital properties of the several parts depend; the degree of that dependence being proportioned to their respective tendencies to spontaneous decomposition if not thus renewed. Still, the vital properties of individual parts may be retained for a considerable period after general or *somatic* death (see DEATH) has taken place; and vital actions may continue, as already stated, so long as the conditions which they require in the living body are supplied. So far from a dead body having "all the organization it ever had whilst alive," as has been often maintained by the upholders of a separate vital principle, it will be found, on a more minute survey, that no single portion of it is existing under the same circumstances in these two states;* and there is good reason to believe that those agents which destroy life with the least apparent organic change, produce structural alterations which are not the less important because more minute. Some instances of this kind will be presently noticed (Sect. V.). We must confess ourselves at a loss to understand how the *gradual* death of individual parts of the body can be explained upon the doctrine of the vital principle, without supposing that it may be split into as many individual existences as there are organs in the system; such an idea would then coincide with that of the *superadded properties* of which we have endeavoured to show the fallacy, and all the arguments derived from the unity of its operations would fall to the ground.

One often repeated objection to the doctrine that vitality results from organisation may, we think, be easily disposed of, as it is more specious than real. It is considered by some to be a sufficient disproof of this doctrine, to refer to the universally-admitted fact, that the existence of organisation implies a previous existence of life; and thence to infer that life cannot be at the same time the *cause* and the *consequence*. But this is a sort of paradox which reminds us of the question that puzzled the profound casuists of yore—"Whether does the bird spring from the egg or the egg from the bird?" It is evident that the life of any individual being may be the consequence of the action of stimuli upon its organism, just as the bird is produced by warmth from the egg; and yet that the organisation of its structure may be the result of the previous existence of life in the parent, just as the egg is produced by a bird. We are only referred backwards, therefore, in our enquiry into the efficient cause of the development of vital properties, to the first creation of each organism. Here some would maintain that the Creator formed a vital principle or organic agent, and then set it to organise the body. But we apprehend that this is an assumption which we have no right to make; and that it is more philosophical, because more consistent with what we elsewhere witness, to suppose that the Creator, in first forming matter, endowed it with properties in virtue of which it became capable of exhibiting vital actions or life, when first combined by Him into an organised structure; and that the Parent of all thus impressed upon the elements of which each created being was composed, the spirit* of the laws which should in future govern its growth and reproduction, just as He impressed upon the bodies composing the planetary system that mode of action whose subsequent continuance has given us the notion of the laws of gravitation and of motion. To account for the perpetuation of the race, we require nothing but the continued operation of those laws; in other words, the continuance of the same mode of action, by which particles of inorganic matter are successively organised, and, *quà* organised, become capable of performing vital actions, a part of which consists in the production of corresponding changes on other materials.

The actions performed by living beings are not all, however, immediately dependent upon the operation of the *vital* properties of their organs; since many are evidently conformable to physical laws, and the properties of the organs by which they are performed are common to them with many kinds of inorganic matter, and are exhibited by dead as well as by living organised substances, as long as no obvious change takes place in their composition. Of this kind are the property of *elasticity* in various tissues, especially certain of a ligamentous character; and that by which *endosmose* takes place through certain membranes. It may be observed, however, that the existence of such properties in the tissues of the living body obviously depends upon a certain arrangement of their ultimate molecules, which can only be maintained by the exercise of their nutrient functions; and that any irregularity in the latter, still more their entire cessation, will speedily impair the properties, by giving free course to the constant tendency to decomposition in the tissues which exhibit them. And further, it may be remarked that in most instances these properties are dependent for their excitement to action in the living body, upon those truly vital processes which no mechanical contrivances or chemical operations can produce or imitate.

Between these two extreme classes of phenomena,—the purely physical, and the purely vital—there is a third, of a very peculiar and perplexing character. We allude to the actions concerned in preparing the *materials for organisation* out of the aliment received into the system. Many are disposed to regard these as of a *vital* character, and to consider that, as

* See Prichard on the Vital Principle, p. 117.

* Herschel's Preliminary Discourse, p. 37.

soon as the living body has begun to change the composition of the substances upon which it acts, it endows them with a new set of affinities, contrary to those which it before possessed when subject to the operations of chemistry. Others, again, are content to refer the operations in question at once to the ever-ready vital principle, which, according to them, produces and directs these changes in the organism, and, so long as it resides there, keeps in check the natural tendency of its structure to decay. We are inclined to believe, on the other hand, that the operations in question are *immediately* due to the agency of the same laws as those which preside over inorganic matter, operating, however, under conditions which the living organism alone can supply. We shall now examine what evidence may be produced in favour of this opinion, and how far it is consistent with the general phenomena of life.

V. Changes in composition.—The alimentary materials which serve as the food of the living organism, cannot be appropriated by its several tissues, and rendered like themselves in structure and properties, until they have undergone certain changes in composition, by which the *proximate principles* are produced. It is by the *organisation* of these compounds, that the constant disintegration of the elementary parts of the living system is compensated, and those vital properties maintained, the exercise of which forms an essential part of the circle of actions involved in life. Another class of changes in composition consists in the production, from the same materials, of the peculiar ingredients which characterise each secreted product; some of these may be regarded as directly eliminated from the nutritious ingredients of the blood, in the same manner as are the solid tissues themselves; whilst others would rather seem to result from the new combination of the disintegrated elements, which are taken up and removed by the current of the circulation, and carried to organs destined to separate them entirely from the living portions of the system. All these changes are frequently said to be effected by a *vital chemistry ;* or (to speak in more precise language) to result from the operation of *vital affinities*, of a different character from those ordinary *chemical affinities* which produce the well-known changes in the inorganic world. In conformity with the Newtonian direction to avoid unnecessarily multiplying *causes*, we shall briefly examine the grounds upon which this hypothesis is based, and enquire whether it is requisite for the explanation of phenomena, or even gives us any assistance in our researches.

The chief ground for the assumption of a distinct set of *vital affinities* appears to be, that the mode of union of the elements of the organic compounds is essentially different from that which prevails in the inorganic world; and that the chemist, who has the power of effecting or controlling those changes which are produced by physical laws, and can therefore imitate to a great extent the immense variety of combinations which the mineral kingdom affords, is unable to effect or control the action of similar materials, so as to produce any of the class of organic compounds or proximate principles. It has, until very recently, been regarded as a distinctive character of organic compounds, that their elements are combined in *ternary* or *quaternary* arrangements of complex nature, in which each ingredient is equally united with all the rest; whilst all inorganic substances admit of being ultimately resolved into simple *binary* combinations. Thus *fibrin* is regarded as composed of 6 parts of carbon, 2 of oxygen, 5 of hydrogen, and 1 of nitrogen; and these elements are imagined to form a quaternary compound, all having a mutual attraction for each other; whilst *carbonate of ammonia*, which consists of 1 carbon, 2 oxygen, 3 hydrogen, and 1 nitrogen, is a binary combination of two other binary compounds, carbonic acid and ammonia. But on this it may be remarked, that there are undoubtedly some *proximate principles*, (that is to say, the simplest forms to which organic compounds can be reduced, without altogether disuniting them into their ultimate elements,) which consist of *two* elements alone, and which exist in this simple form in living bodies. Such are some of the compounds of carbon and hydrogen. Further, the rapid progress of analytic research is leading to the belief that the complex arrangements just referred to may be resolved into those of a binary character; so that most organic compounds may be regarded as resulting from the union of others of simpler nature, just as a salt is formed by the union of an acid and an alkali. The discovery of cyanogen, and of its capability of acting as a *compound radical*,—uniting, like chlorine or iodine, with hydrogen to form an acid, and even occasionally serving, like oxygen or sulphur, in combination with some metals, as the base or alkali to such an acid,—was the first step in a career of brilliant discoveries, which, even at the present day, may be regarded as scarcely commenced. When cyanogen combines with a metal, the combination is in reality a *ternary* one, although in all its properties it has a binary character. Thus, the cyanuret of silver (whose ultimate composition is 1 part of the metal, with 2 carbon, and 1 nitrogen,) will form a salt, in which it acts as the acid or negative ingredient, with the cyanuret of potassium; and the soluble cyanurets will form salts with the chlorides or iodides of the metals, thus establishing their claim to a binary character. But still further;—cyanogen in combination with iron appears itself to act as a *compound radical*, combining as a *simple* body with other elementary substances.* From the analogy afforded by this and other instances, many chemists are now disposed to look upon the combination of the oxy-salts in a new light. It is suspected that, when sulphuric acid and soda are brought together, the resulting compound is not formed by the union of an atom of the acid with an atom of the alkali, but by the generation of a new compound radical, *sulphatoxygen*, consisting of 1 part of sulphur with 4 of oxygen, which unites

* Liebig, in Turner's Chemistry, 6th ed. p. 776.

as a simple body, like chlorine, iodine, or cyanogen, with the metal sodium.*

It will be seen, then, that the tendency of modern researches in inorganic chemistry is to prove, that the mode of combination which characterises the union of its elements, is not by any means so simple as it has been usually supposed; but that a binary, a ternary, and perhaps even a quaternary compound, may perform the part of an element, combining with other elements which are really simple, to form what are regarded as simple binary compounds. We shall now enquire what reason there is for believing that the compounds with which organic chemistry supplies us, have a similar constitution. We must be content, however, with selecting one or two examples from among the vast number which the industry of analytic chemists is constantly bringing to light. The vegetable *alkaloids* have been generally regarded as *proximate principles*, not to be separated into simple compounds without an entire disunion of their elements. They all contain one equivalent of nitrogen; and there is good reason to suspect that this element is not equally combined with all the rest, but exists in union with hydrogen in the form of ammonia, to which the alkaline power of these substances is due. Again, camphor was long considered a proximate principle of ternary composition; but it is now found to be an oxide of *camphene*,—a compound radical consisting of carbon and hydrogen, which will unite, like cyanogen, with simple bodies; forming camphoric acid with another equivalent of oxygen, and entering with chlorine, &c. into other compounds. Lastly, *urea* may be mentioned, in which the four elements that compose it may be regarded as existing in several forms of binary combination. It contains these elements in the following proportions:—2 oxygen, 4 hydrogen, 2 carbon, and 2 nitrogen. These may be considered as existing in the form of cyanic acid, ammonia, and water; one equivalent of each of these forming cyanate of ammonia; and, in fact, by the artificial union of these compounds, *urea has actually been produced*. It is by no means certain, however, that these compounds exist *as such* in urea; and various ideas of its composition are entertained by chemists, on which this is not the place to comment. Our object is simply to show the analogy in the composition of the products of vital chemistry with that of the artificial compounds whose formation is subject to none but physical laws. Why the chemist is not more successful in imitating in his laboratory the operations of the living economy, will presently become subject for consideration.

An argument employed by many physiologists for the existence of a distinct set of vital affinities, is founded upon the evident truth, that the tissues and fluids which maintain a certain composition when possessed of vitality, speedily resolve themselves into new combinations when this has become extinct. Hence it is inferred that the affinities which hold together the elements during life, are of a different nature from those which operate in producing their subsequent separation. Now, it may be objected to this inference, that no solid or fluid compounds which have a disposition to spontaneous decay after death, can continue to exist without change during life; that the activity of the processes of interstitial absorption and reposition seems to bear a pretty constant ratio, in every case, with the natural tendency to decomposition; and that the maintenance of the original combination is not so much owing to anything peculiar in the affinities which hold together its elements, as to the constant removal of particles in a state of incipient decay, and their replacement by others freshly united. Thus, we find that all the most permanent parts of the animal frame, such as the massive skeletons of the polypifera, the calcareous tegument of the mollusca, or the bony scales of fishes, to the possible duration of which geologists scarcely dare to assign a limit, are extravascular in the living animal, undergoing scarcely any interstitial change when once formed. Next to these in order of durability are the osseous structures of animals, and the woody fibre of plants, whose connection with the circulating system appears rather adapted to meet the exigencies of growth, injury, or disease, than to maintain a constant change required by the tendency to decomposition. When we examine the softer tissues, on the other hand, we find that the rapidity of interstitial change fully compensates for the increased tendency to decay; and that the perfect exercise of their respective functions imperatively demands the constant maintenance of their normal constitution. Moreover, there are many organic compounds which are as permanent as those formed in the laboratory of the chemist; of this kind are gum, sugar, and many other proximate principles, which simply require for their preservation such external conditions as are necessary to prevent the spontaneous decomposition of many inorganic bodies. The degree in which these are subject to ordinary chemical operations will be presently mentioned. It appears, then, to be an inference better founded on fact than that first mentioned, that the preservation of the normal constitution of organic compounds in the living body, is dependent on the continuance of the vital actions of the economy, rather than due to its mere possession of the property of vitality. In fact, *that* may be reasonably maintained as an inference from these phenomena, which we have already attempted to prove on other grounds;—that the vitality of each tissue, that is to say, its possession of vital properties, is dependent on the perfect condition of its organisation, and that, so far from preserving the organism from decay, it merely remains until decay has commenced. These inferences are, we think, fully borne out by the two following facts. When life is being extinguished by starvation, the whole body exhales a putrid odour even before the occurrence of death, and rapidly passes into putrefaction afterwards: here it would seem that the process of spontaneous decomposition, which we have

* See Graham's Chemistry, p. 158 et seq.

represented as constantly occurring in the tissues, has been unbalanced by the reposition of nutrient materials; and that it has therefore manifested itself in the body even during life. Again, when spontaneous gangrene occurs from obstruction to the circulation, decomposition slowly supervenes in the part from which the supply of nutrient fluid is cut off; and *coincident* with its progress is the extinction of the vital properties, constituting molecular death. (See vol. i. p. 791.) Corresponding changes may result in the whole body when the nutritive functions are interrupted, not by obstruction to the motion of the circulating fluid, but by depravation of its character; and we then perceive the vital properties of each tissue impaired in a degree correspondent to the dependence of the integrity of its structure upon the constant renewal of its elements.

The presumed impossibility of forming, by the chemical combination of their elements, any of the class of *organic compounds* or *proximate principles*, is regarded by many physiologists as in itself a sufficient ground for the assumption that the affinities which act in the living body are different from those which we recognize in the inorganic world. The fact, however, which we have already noticed regarding the artificial production of *urea* is one which powerfully opposes such an assumption.* This is slurred over by Müller, with the remark that it can scarcely be considered as organic matter, being rather an excretion than a component of the body—a distinction which does not remove it from the pale of the operation of the supposed laws of vital affinity. Seeing the vast progress which organic chemistry has made during the last few years, and the rapid increase of our knowledge regarding not merely the composition but the mutual relations of the class of bodies under consideration, we cannot but think it premature to assert that other compounds may not be produced in a similar manner. Be it observed, however, that the doctrine for which we are now arguing only concerns the production of those compounds which are destined either to be thrown off from the system, or to undergo subsequent organisation; and cannot apply to those in which the process of organisation, and the consequent development of vital properties have already commenced. This distinction is a very important one, and may, we think, by being kept steadily in view, save much unsuccessful because mis-directed labour. If, for example, our view be correct, it may be possible for the chemist to produce the gum or sugar which he finds in the ascending sap of plants; but he can never hope to imitate the latex or elaborated sap, which already shows traces of organisation and of the possession of vital properties. In like manner the formation of albumen may be a worthy object of his endeavours, whilst these would be totally fruitless if directed to the production of fibrin, which differs from it but little if at all in chemical constitution, but which is endowed in its fluid state with properties that nothing but the influence of a living system can generate.

But quitting these speculations, we shall inquire what positive evidence may be produced of the operation of chemical affinities in the changes of composition that form so important a part of vital action. Many facts might be collected which favour such a belief; but the following must here suffice. In the progress of vegetation we have frequent occasion to observe the conversion of gum and of fecula, which consists of gum enclosed in vesicles, into sugar. This takes place in germination, in the budding of the potato and other fleshy stems, in flowering, in the ripening of fruit, as well as in many other instances; in all these in which fecula is the subject of the change, it would seem that this product, having been stored away out of the current of the circulation against the time of need, is to be again brought into use, and to supply the pabulum of young or rapidly-growing parts by conversion into sugar. These changes are effected in various modes. Where gum is the subject of the conversion, we commonly find an acid employed to produce it, as in the ripening of fruits, where lignin as well as gum seems to undergo this change. The chemist can produce the same effect by digesting gum or lignin with an acid at a certain temperature. Again, where the conversion of fecula into sugar takes place as one of the ordinary processes of the vegetable economy, it is effected by the production of a secretion termed *diastase*, which occasions both the rupture of the starch-vesicles and the change of their contained gum into sugar. This diastase, which is abundantly stored up in the neighbourhood of the eyes or buds of the potato, may be separately obtained by the chemist; and it acts as effectually in his laboratory as in that of the vegetable organism. Further, he can imitate its effects by other chemical agents; for, by the joint operation of heat and acid, he can produce the same transformation.

These are among the remarkable instances of the *catalytic* action recently described by Berzelius,* which is common to organic and inorganic operations, and which is not yet found to be comprehensible within the known laws of chemical affinity. The peculiarity of the action consists in the production by one body, A, of a change in the composition of another, B C, without itself undergoing any alteration. Thus, the peroxide of hydrogen, which is readily decomposed by any substance having an affinity for oxygen, is also decomposed by some which themselves undergo no change, such as the metals and the fibrin of the blood; these produce in it a state analogous to fermentation, oxygen escaping and water being left. Again, not only decompositions but new combinations may be effected in this manner. Thus, most metals at high temperatures, and platinum in a state of minute division at low temperatures, as well as various porous sub-

* We do not quote any others reported to possess the same character, such as the production of fatty matter by Berard and Hatchett, because they still require confirmation.

* Edinb. Phil. Journal, vol. xxi.

stances slightly heated, produce the union of oxygen and hydrogen in an explosive mixture. The action of sulphuric acid on alcohol in producing ether, without itself undergoing change, appears referable to the same class along with those just described. We may consider it proved, then, that many substances possess the power of exercising upon compound bodies an influence essentially distinct from what is known as chemical affinity—an influence which consists in the production of a displacement and new arrangement of their elements, without themselves directly participating in it. Assuredly such a power, which is capable of effecting chemical reactions in inorganic substances as well as in organised bodies, though still too little known to be accurately explained, must play a far more important part throughout nature than we have hitherto been led to suppose. "In defining it a new power," says Berzelius with philosophic caution, "I am far from wishing to deny that some connexion exists between its influences and the electro-chemical ones with which we are familiar. On the contrary, I am very much disposed to recognize it as a peculiar manifestation of these same influences."*

Another interesting series of facts, which seem to confirm the theory of the operation of chemical affinity in the living body, is that which relates to the evolution of electricity during the ordinary processes of growth both in plants and animals. The late researches of Dr. Faraday have fully proved the identity of electrical attraction with chemical affinity, and have shown that all chemical changes are attended with a disturbance of electric equilibrium. If, therefore, the changes occasioned by the growth of organised systems are immediately governed by laws similar to those which preside over inorganic matter, we should expect to find that electricity is constantly being developed by them in the same manner as we obtain it by chemical decomposition or recomposition. There is no deficiency of evidence that such is the case, as the results of late inquiries most abundantly testify.†

That chemists have not been more successful in imitating the operations of vital chemistry, by the artificial production of organic compounds, is due not only to their ignorance of the composition of such bodies, but to their want of acquaintance with the *form* or *condition* in which they must be brought together, in order to enter into the desired union. Every one conversant with chemical operations is well aware of the important influence thus exerted. A slight change of temperature, for example, often reverses the affinities of a body; and many elements are susceptible of particular actions when in a *nascent* state (*i. e.* when in the act of being freed from some other combination) which in their ordinary condition could not be so affected. When it is considered, therefore, how little we know of the operation of such conditions in the laboratory of life, no surprise will be felt that its results should often appear contrary to what might have been anticipated. No reasonable ground has yet been adduced for supposing that, if we had the power of bringing together the elements of any organic compound in their requisite states and proportions, the result would be any other than that which it is found to be in the living body; for the agency of vitality, as Dr. Prout justly remarks, "does not change the *properties* of the elements, but simply combines them in *modes* which we cannot imitate."

It is hoped that the foregoing statements will have established the probability (which is all that the present state of our knowledge on these subjects will allow us to assert) that the affinities which hold together the elements of living bodies, and which govern the elaboration of organic products, are the same as those constantly operating in the world around. It would seem, at any rate, premature to assert that the operations of vital chemistry are directed by distinct laws and due to new forces. The designations *organic* and *vital affinity* seem to have been employed by some writers to express only the peculiarities of the circumstances and conditions under which these laws usually operate, rather than any real difference in the nature of the powers themselves. And others appear to use them as *provisional* terms only, referring those effects to the operation of vitality which chemistry is not yet in a condition to explain. In the former sense it is manifest that such employment of the term is injurious as leading to misconception. In the latter it is harmless, if it do not check inquiry and create a prejudice against the reception of new facts. The period when all difficulty shall have vanished from the application of chemical laws to the phenomena of the vital economy may be very far distant; and in the mean time "we must be content with gathering a few indications which occasionally break out from the clouds of mystery in which the subject is obscured." But it must not be left out of view that every fresh discovery adds to the number of these indications, and that they all point in the same direction; so that the probability of the universal operation of chemical affinity in the living body becomes every day more strong, and the difficulty in proving the existence of a distinct set of vital affinities is constantly becoming less easily surmounted.

VI. Vitality in a dormant or inactive condition.—There are many organised beings at particular periods of whose existence all *vital action* seems to be suspended; and this may result either from the absence of the stimuli necessary to maintain it, or from some change in the organism itself, by which it becomes for a time less capable of responding to these stimuli. When vital action is suspended from the deficiency of external stimuli, one of two things must happen; either the vitality of the organism will be destroyed by the disin-

* This eminent chemist has been quoted as an advocate of the doctrine of vital affinities. If such was formerly held by him, it is evident, from the tenor of the communication here referred to, that he has abandoned it.

† See the Author's essay on the laws regulating vital and physical phenomena, in Edinb. Philos. Journal for April 1838; and Principles of General and Comparative Physiology, p. 379 *et seq.*

tegration of its tissues; or it may be preserved in consequence of the absence of those agents which ordinarily excite decomposition. The occasional suspension of vital action from a change in the organism itself, appears usually to result from a general law of *periodicity*, which affects, more or less, all organised beings, producing the phenomena of sleep, hybernation, &c.; but it may also arise from particular causes operating within the system, as in syncope. Each of these cases will now be separately considered.

Dormant vitality of seeds, eggs, &c.—The condition of organised beings of which we have first to treat—that in which *vital action* is suspended from the absence of the stimuli necessary to maintain it, and *vitality* nevertheless preserved—is manifested in the most remarkable manner by the reproductive germs which are periodically separated from plants and animals, and which are endowed with the power of developing themselves into new individuals when the requisite conditions are supplied to them. In the lowest classes of each kingdom, it would appear that these germs are liberated from the parent unprovided with any means for the continuance of their development; and that from the first, therefore, they rely upon the surrounding elements for *all* the conditions of their active existence. It is beautifully provided that, in proportion to the probable deficiency of some of these, should be the tenacity with which the apparently lifeless germs retain their vitality. The sporules of the fungi, which can only subsist on decaying organised matter, seem universally diffused through the atmosphere, and ready to vegetate with the most extraordinary rapidity whenever a fitting nidus is afforded for their development. This, at least, appears the only feasible mode of explaining their appearance in the forms of mould, mildew, &c. on all decaying surfaces; and that there is no improbability in the supposition itself is shown by the estimate of Fries, who states that a single individual of *reticularia maxima* will emit above 10,000,000 of these germs, so minute as when collected to be scarcely visible to the naked eye, rather resembling thin smoke, and so light as to be wafted by every movement of the atmosphere, so that, he remarks, "it is difficult to conceive a place from which they can be excluded." It seems more than probable that in a similar manner is to be explained the appearance of infusorial animalcules in all situations adapted to their existence; and that their germs are constantly and universally diffused through the air, ready to commence the active exercise of their dormant properties whenever they meet with the stimuli to their development afforded by warmth, moisture, and decomposing organic matter.*

We have no means of ascertaining the length of time during which this dormant vitality may be preserved. It would be difficult to assign a limit to it, since it is scarcely conceivable that any change can occur in the structure of these minute desiccated points which they do not undergo during the first few hours of their aerial residence; and we have no reason to believe that vitality can be destroyed without change of structure. With regard to the seeds of phanerogamic plants, we have more certain evidence, and this of a very interesting character. It is to be remarked, however, that in them, as in the eggs of higher animals, there is, besides the germ itself, a reservoir of nutriment supplied by the parent, which enables the germ to continue its development up to the point at which it becomes fit to maintain its own existence, without any other than the ordinary assistance of vital stimuli. The germination of a seed, for example, requires only warmth, moisture, and the access of air, and is further accelerated by the absence of light; and the hatching of an egg is dependent only on a temperature more or less elevated and the presence of air. Hence the necessity for so great a tenacity of vitality as that possessed by the germs of the simpler classes does not exist, and although under favourable circumstances the vitality of seeds may be prolonged for an almost indefinite period, they are more susceptible of the injurious influence of external agents, and their fertility is destroyed by changes of condition which would have no effect in the former case; whilst the eggs of animals appear still less tenacious of vitality, although in a few instances capable of retaining it for some time, even under considerable disadvantages, as will be presently noticed.

The seeds of most plants which inhabit temperate climates are adapted to remain dormant during the winter, and may be preserved in dry air and moderate temperature for a considerable time. Some of those which had been kept in the Herbarium of Tournefort for upwards of a century were found to have preserved their fertility. But with regard to those which are brought from tropical climates there is greater uncertainty, and unless they have been carefully excluded from the contact of air and from variations of temperature, a large proportion are usually unproductive. Cases are of no unfrequent occurrence in which ground that has been turned up spontaneously produces plants dissimilar to any in their neighbourhood. There is no doubt that in some of these the seed is conveyed by the wind, and becomes developed in spots which afford congenial soil, in the same manner as the germs of fungi and infusoria. Thus it is commonly observed that clover is ready to spring up on soils which have been rendered alkaline by the strewing of wood-ashes, or the burning of weeds; and it is stated by Professor Graham that after any hill-pasture in Scotland has been laid dry and limed and the surface broken, white clover always makes its appearance. But there are many authentic facts which can only be explained on the supposition that the seeds of the newly-appearing plants have lain for a long period imbedded in the soil, at such a distance from the surface as to prevent the access of air and moisture, and that, retaining their vitality under these circumstances, they

* For an important experiment on this subject recently performed by Schultz, see Edinburgh Philosophical Journal, Oct. 1837.

have been excited to germination when at last exposed to the requisite conditions.*

Most physiologists, at least, are content to adopt this explanation, seeing that it is conformable to what is otherwise known of the persistence of vitality in seeds; but it has been recently maintained that in such instances a *spontaneous production* takes places, similar to that which many philosophers have supposed to occur among the lower tribes of organised beings.† This is not the place to discuss such a theory, of which it would not perhaps be very difficult to show the absurdity; but the following case furnishes, we apprehend, a very satisfactory proof that seeds may preserve their vitality for an unlimited time, when the external conditions are such as to prevent either the active exercise of their properties or the disorganisation of their structure. "I have now before me," says Professor Lindley,‡ "three plants of raspberries which have been raised in the gardens of the Horticultural Society, from seeds taken from the stomach of a man, whose skeleton was found thirty feet below the surface of the earth, at the bottom of a barrow which was opened near Dorchester. He had been buried with some coins of the Emperor Hadrian, and it is probable, therefore, that the seeds were sixteen or seventeen hundred years old."

In regard to eggs, no such examples are, we believe, on record; nevertheless, there are some tribes of animals whose eggs are capable of being preserved for a considerable length of time, and of undergoing very severe treatment without loss of their vitality. Most insects deposit their eggs sufficiently early in the summer for the larvæ to be hatched and attain their full growth before the autumn deprives them of their supply of food, and these pass the winter in the pupa state. But there are some which do not begin to lay until the activity of vegetation has nearly ceased, and their eggs remain undeveloped until the ensuing spring arouses both the animal and vegetable creation into life. The curious instincts which lead these insects to choose secure places for the deposition of their eggs, and to use other means of protecting them against cold and moisture, are described by Mr. Kirby;§ and the same author points out the beautiful correspondence between the temperature required for the development of the buds of the plant and of the larvæ that prey upon them. It has been mentioned in a former article|| that the eggs of the slug are capable of enduring a temperature of 40°, and of being completely desiccated, without losing their fertility; and it can scarcely be doubted, therefore, that these might preserve their vitality like the seeds of plants for an unlimited period, if neither aroused into activity nor disorganised by decomposing agents.

It will scarcely be denied that the agents which are known to destroy the vitality of seeds and eggs are such as are calculated to produce important changes in their structure and composition, even though these be of a kind inappreciable by our present means of research. Thus most seeds are killed by a temperature of 160°, which is that at which rupture of the vesicles of fecula takes place, and the application of heat sufficient to destroy the vitality of an egg coagulates its albumen. An electric shock is well known to be a powerful means of instantaneously extinguishing the vital properties of eggs or seeds; and although the precise alterations which it effects in the structure or composition of their parts is not understood, it cannot be doubted that important organic changes are produced by so powerful an agent. Cold, in like manner, probably acts injuriously on most eggs and seeds as upon plants, by causing the rupture of the cells of their tissues through the expansion of the contained fluids in the act of freezing. We do not mean to say that *other* changes are not also produced by such agents, but we mention these as evidences of the position with which we started—that vitality is not destroyed by the influence of external agents without a structural change of some kind being induced by their operation.

But it is not during their embryo state merely, that the vital actions of living beings may be suspended by the deficiency of external stimuli, and yet their vitality be preserved. Both the vegetable and animal kingdoms afford numerous examples of such an occurrence at all periods of existence, especially among their lower tribes. Mosses, for instance, often appear completely desiccated in dry weather, and seem as if dead; whilst, on the application of moisture, they revive in all their pristine beauty. The curious Lycopodium of Peru exhibits this torpor in a still more remarkable manner. When desiccated by drought, it folds in its leaves and contracts its roots so as to form a ball, which, apparently quite devoid of animation, is driven hither and thither by the wind; as soon, however, as it reaches a moist situation, it sends down its roots into the soil, and unfolds to the atmosphere its leaves, which, from a dingy brown, speedily change to the bright green of active vegetation. The rose of Jericho is the subject of similar transformations. Instances exactly parallel are furnished by the animal kingdom. The common wheel-animalcule is one of the most remarkable, being capable of desiccation so complete as to splinter if touched with the point of a needle, and still preserving its vitality so as to revive when moistened.* In animals reduced to a

* For several cases of this kind related on the authority of Professor Graham, see Dr. Prichard's Physical History of Man, third edit. vol. i. p. 39, &c.; and for a very curious instance communicated to the author of this article, see his Principles of General and Comparative Physiology, p. 141.

§ Kirby and Spence's Entomology, vol. ii. p. 443.

|| Vol. ii. p. 402.

* This fact has been denied by some naturalists; but the author can positively assert it from his own experience. See Principles of Gen. and Comp. Physiology, p. 90, *note*. From experiments subsequent to the one there related, he is inclined to believe that of two species of *Rotifer*, so nearly allied as to be usually considered the same, one is thus revivifiable, and the other not.

state of torpidity by cold, some vital action usually continues; and such cases cannot therefore be adduced under the present head. But instances are by no means rare in which the whole body has been frozen, and vital action has of course been completely suspended, yet without the destruction of the power of renewing them under more favourable circumstances. Lister first noticed that he had found caterpillars so frozen, that when dropped into a glass they chinked like stones, but nevertheless revived; and this statement has been confirmed by Bonnet and others. The *Papilio Brassicæ* has been produced from a larva which had been exposed to a frost of 0° Fahr., and which had become a lump of ice. Fishes are occasionally found imbedded in the ice of arctic seas; and some of these revive when thawed. This tenacity of life appears greater, however, in the species which are confined to shallow lakes or ponds, and which have not the power, therefore, of escaping from the effects of cold. This is perhaps the proper place to mention those undoubted cases in which insects have been apparently killed by immersion in water or spirit, continued for a long period, and have yet revived on exposure to the air and sun.

Without multiplying facts, then, it may be safely affirmed that many organised beings may retain their vital properties, in some instances to an unlimited duration, while all vital activity or life is completely suspended, through the absence of the stimuli necessary to maintain it; and that this preservation of vitality bears so close a relation to the resistance offered, by the structure and composition of the substance possessing it, to the influence of disintegrating agents, that it may reasonably be considered as a *result* of the maintenance of its normal constitution. The physiologist is not yet in a condition to explain those differences in structure and composition which enable some organisms to offer a much greater resistance to such injurious influences than others; but he considers himself entitled to assume that such exist in all, since there are many instances in which he is able to detect them.

Suspension of vital action under other circumstances.—We have next to consider those cases in which vitality is rendered for a time dormant, by causes originating in the system itself, rather than by the withdrawal of external stimuli. Under this head we may place all those phenomena to which the name of *hybernation* is usually given; but which, as will presently be seen, cannot be appropriately designated by that term. The greater number of plants indigenous to temperate climates undergo an annual series of phases, in which their vegetative processes exhibit every gradation from a torpor apparently complete to the most surprising activity. In many, indeed, this series of phases constitutes the whole of life; the individual ceasing to exist as soon as it has been once performed, and a new generation called into existence. In many more, a total suspension of activity appears to take place, as may be observed in plants whose stems die annually, whilst the roots retain their vitality. This condition exactly resembles that of certain animals which pass the winter in a state of profound torpor. In those, however, whose stems are woody and persistent, vital action does not seem to be completely checked even by a frosty atmosphere; as late experiments show that a movement of sap takes place, though to a trifling degree, in the depth of winter. And, lastly, in evergreen plants, these changes of condition are less complete; the activity of the vegetative processes being diminished by the partial withdrawal of their appropriate stimuli, but not being altogether suspended. Now although it is unquestionable that this series of changes is greatly *influenced* by the successive alterations in the external conditions of the beings, which the revolution of the seasons induces, it does not admit of doubt that it is originally *dependent* on the peculiar constitution of the organism, by which a *periodical* diminution of its activity is occasioned. For nothing will prevent a plant from shedding its leaves nearly at its usual time; and although by artificial heat, or by removal to a warmer climate, a new crop may be brought out within a short interval, this can only be effected by keeping in a state of activity the processes which ought to be at rest, so that an injurious influence is exerted on the general system like that which results from artificially-prolonged watchfulness in animals. When a plant is reduced, by the periodical decay of its stem and leaves, to the state of a bulb or root, it seems almost to revert to that remarkable condition already described as peculiar to seeds; the vitality of the structure being capable of remaining dormant for a considerable time, and of being then aroused into full activity by the appropriate stimuli. We are not aware of any authentic facts which fix the limit to the duration of this condition. Instances have been related of the growth of bulbs unrolled from the envelopes of Egyptian mummies; but there is reason to believe that deception has been practised on this point upon the too-ready credulity of travellers. However, there can be no doubt that, under favourable circumstances, bulbs and roots may be preserved for many years; the conditions necessary for this object being such as neither excite the vitality of the structure to action, nor occasion the disintegration of the latter and the consequent loss of its properties.

The animal kingdom presents us with conditions very analogous to those just alluded to. In a large proportion of those inhabiting temperate climates, there is a periodic diminution of vital activity during the colder part of the year; but this, in the higher tribes at least, scarcely amounts to an absolute suspension, since the circulation, and the functions of nutrition and secretion which depend on it, are carried on, though feebly. (See Hybernation.) It is easy to understand why this must be the case. The softer portions of the animal frame, which are most concerned in the processes of organic life, are not periodically cast off and renewed like the corresponding parts of plants; and, if their integrity were not maintained by the circulation of nutritious fluid during their inactive state, their normal constitution would be soon affected by their proneness to decomposition, and their peculiar properties be consequently lost. Amongst cold-blooded animals, however, we find instances of more complete suspension of vital actions, which may even be prolonged for a considerable period. Thus, Spallanzani kept frogs, salamanders, and snakes, in a torpid state, in an ice-house, where they remained three years and a half, and readily revived when again exposed to the influence of a warm atmosphere. Insects, in their pupa state, may be regarded as analogous to plants reduced to bulbs. Although the duration of this torpid condition is ordinarily determinate for each species, and although some changes occur during its continuance which scarcely warrant us in characterising the state as one of entire inactivity, there are some instances which prove that it may be prolonged for an almost indefinite period, under particular circumstances. The degree of temperature to which pupæ are exposed seems to have the same kind of influence over them as on the eggs of insects. Thus Reaumur found that pupæ, which would not naturally have been disclosed until May, might be caused to undergo their metamorphosis in a fortnight during the depth of winter, by the influence of artificial heat; and, on the other hand, that their change might be delayed a whole year beyond its usual time, by the prolonged influence of a cold atmosphere. We can scarcely imagine, however, that temperature is the *sole* agent in accelerating or retarding the final metamorphosis. If the caterpillar of *Papilio Machaon*, one of those which has annually a double brood, becomes a pupa in July, the butterfly will appear in thirteen *days*; if not until September, it will not make its appearance until the June following, that is, not in less than nine or ten *months*. Here it is evident that the torpor has been prolonged from some cause inherent in the system itself, for the purpose of preventing the disclosure of the butterfly at too early a period of the season. A still more curious proof of this tendency to prolonged torpidity during the pupa state is the following. If a number of the pupæ of the *Eriogaster lanestris*, a moth whose larvæ are common on the blackthorn in June, be selected at the same time, and placed in the same circumstances, the greater number of them will disclose the perfect insect in the February following; some not until the February of the year ensuing; and the remainder not before the same month in the third year. The same has been observed of the *Arctea mendica*, of which thirty-six pupæ, grown from eggs laid by the same parent, produced twelve perfect insects in each of the three following seasons.* The *final cause* of this curious tendency may be, as surmised by Mr. Kirby, to secure the race from being cut off by unfavourable seasons, or by some extraordinary increase of its natural enemies. But its *efficient cause* can only be looked for in some modification of the properties of the organism analogous to that which produces the phenomena of hybernation in other animals. The same *periodicity*, manifesting itself, not in obedience to a diminished temperature, but at the season of greatest heat, is observed in tropical climates. Many tribes of insects in the torrid zone seem to retire to places of retreat during the parching droughts of summer, and make their appearance again during the rainy season, when vegetation is in the highest luxuriance. We here trace the same beautiful adaptation of the phases of animal and vegetable life as in the former instances; but the efficient cause which induces these changes must be different.

Our limits do not allow us to dilate upon one very interesting department of this subject —the prolongation of dormant vitality under particular circumstances in frogs and other reptiles. Many marvellous stories of this kind are on record;—such as the inclosure of these animals in solid blocks of granite or other igneous rocks, which no well-informed person can credit. There are, however, a sufficient number of authentic cases to prove, in the estimation of those who have fairly examined them, that toads and other reptiles may be enclosed in masses of rock *apparently* solid, or in the substance of the trunks of trees, and that they may preserve their vitality under such circumstances for a very long period. In the former instances, it would appear that the animal has fallen into a chink or crevice, which has been gradually filled up by the washing-in of gravel or other materials disposed to solidify; and that thus the appearance of a solid mass has been given, when in reality some communication has existed between the cavity and the external air. It is by no means impossible, moreover, that these animals might be found imbedded in the sandstones at present in course of formation in many localities; these rocks possessing considerable hardness, but being at the same time sufficiently porous to allow of the slow passage of air through their substance. Where toads have become imbedded in crevices of trees, and been surrounded by new layers of wood, it is evident that a direct communication with the atmosphere will probably exist by means of the original crevice, although it may be much narrowed; but even if this be not the case, the porosity of the wood will furnish the required condition. Some amount of access of air would seem, from the experiments of M. Edwards and Dr. Buckland, to be essential to the prolonged vitality of toads enclosed in solid masses; and this will probably maintain a very feeble respiratory action upon the blood through the general surface, just sufficient to prevent the decomposition of the body. Vital action cannot, therefore, be regarded as so completely extinct under these circumstances as in some of the cases formerly mentioned, where the application of cold has not only completely checked it, but has also done away with the necessity for it, by completely subduing the tendency to decomposition.

In the human economy, as in that of other

* Kirby and Spence's Entomology, vol. iii. p. 266.

non-hybernating animals, it is only occasionally that anything approaching to this suspension of vital action can occur. That which takes place during sleep only relates to the sensorial functions; the organic changes experiencing but little diminution in activity. The closeness of the connection between their vital operations, and the immediate dependence of these upon external stimuli, involve the destruction of life when they are totally withdrawn; and it is only under peculiar conditions of the organism itself, that we ever witness a suspension of vital action without the speedy supervention of death. Indeed it may be fairly questioned whether such suspension can ever *completely* take place; and whether the changes which occur in the periphery of the circulation are not continuing, however feebly, even when no action can be detected at the centre. This condition is termed *syncope;* and its phenomena will be more fully detailed hereafter. (See SYNCOPE.) We are inclined to think that, where a state of apparent death has continued for some days, vital action was never entirely suspended; though perhaps its cessation may be more complete where the syncope is but transient. Such would seem to be the case where individuals have recovered from a submersion under water, which has been prolonged beyond the few minutes that suffice to produce asphyxia. It is generally supposed, and we think with reason, that the mental emotion experienced at the moment of submersion produces a state of syncope; and that the organism, being in that state less dependent on external stimuli than when in a more active condition, can bear privations which would be otherwise fatal, just as is known to be the case with hybernating animals, the pupæ of insects, &c. The well-known case of Col. Townsend appears to us to prove that an apparent cessation of vital action does not imply its entire extinction; since when no changes could be detected by his medical attendants, he was voluntarily acting on his system both to retard and renew its usual functions. Dr. Cleghorn of Glasgow knew an individual who could control the action of his heart, so as to be able to feign death at pleasure.

Although in these cases we may be disinclined to admit the *total* suspension of vital action, there can be no doubt that it may occur in *portions* of the human body under the influence of cold, and that, if carefully treated, it may be again renewed. Nay more;—there is undoubted evidence that portions of the body, after being totally separated from it, may be reunited and made again to form integrant parts of the structure, if no disorganisation has taken place in the interval. That such an occurrence is perfectly consonant with the doctrines which we have maintained regarding the connection between vitality and organisation—will be at once evident; but we do not see how it can be satisfactorily explained by the advocates of the doctrine of a separate life or vital principle. Does the finger or nose which has been cut off carry with it a chip or off-shoot of the parent vital principle or organic agent? If so, when does that quit its material tenement? There is no evidence of its existence in the separated part, which is completely dead to the general structure, and which nothing prevents from speedy decay, if its vital actions be not soon renewed. And if it be supposed to remain, it must again become merged in its parent principle, when re-union of the divided parts has taken place, or must submit to it like a dutiful child. There is no end to the absurdities in which those may be involved, who adhere with pertinacity to a doctrine so useless and so unphilosophical as that of a single controlling agent or power, presiding over the affairs of each organism.

It is with much satisfaction that the author of the foregoing article (which was written above a year ago) refers his readers to the recently published *Supplement on the Atomic Theory*, by Dr. Daubeny, for a full discussion of the question briefly considered in § V. The conclusions at which the learned Professor has arrived are of precisely the same character as those for which the author has here argued, and are expressed in almost the same language. The following passages may be extracted from among many of great interest.

" There is little doubt that it will eventually appear, that all the secretions or excretions of animals and vegetables are only so far dependent upon life, inasmuch as, in consequence of the favourable temperature which it sustains, the constant circulation of the fluids it occasions, and their exposure to external agents in vessels of different shapes and dimensions, a mechanical separation of the ingredients of the blood is effected in some instances, and a chemical change produced in its composition by catalytic action in others." "The putrefaction of vegetable and animal matters appears to be produced, not by any sudden cessation of those affinities which had previously bound their respective elements together, but by the predominance over them of the natural forces, which we may without much difficulty conceive to have been controlled under the circumstances in which the living body is placed; nor does there seem any sufficient reason for calling in the intervention of an occult principle to explain that, to the solution of which by known causes, every fresh advance in chemical knowledge seems to bring us into closer approximation." " It is now certain that the same simple laws of composition pervade the whole creation; and that, if the organic chemist only takes the requisite precautions to avoid resolving into their ultimate elements the proximate principles upon which he operates, the results of his analysis will show that they were combined precisely according to the same plan as the elements of the mineral bodies are known to be."

LIVER, Normal Anatomy.—Syn. Gr. ηπαρ; Lat. *jecur*, *hepar*; Fran. *foie*; Germ. *Leber*; Ital. *fegato*. The liver is a conglomerate gland of large size, appended to the alimentary canal, and performing the double office of separating certain impurities from the venous blood of the chylopoietic viscera, previously to its return into the general circulation, and of secreting a fluid necessary to digestion—the bile.

It is *situated* in the abdomen, in the right hypochondriac region, and extends across the epigastrium into the left hypochondriac region. Superiorly it ascends to a level with the sixth or seventh rib, diminishing the cavity of the chest on the right side, and inferiorly it approaches by its anterior border, the lower margin of the thorax.

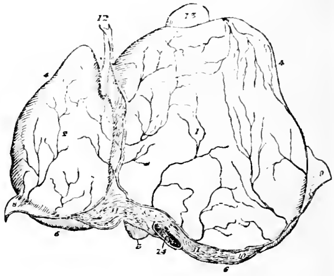
The general *form* of the liver is flattened, being broad and thick towards the right extremity, and narrow and thin towards the left. Glisson compared its shape to the segment of an ovoid cut obliquely in the direction of its length, and Dr. Alexander Monro to the hoof of an ox rounded superiorly. Its superior surface is convex; the inferior irregularly concave; the posterior border is thick and rounded, and the anterior thin and sharp.

Its *position* in the abdomen is oblique, the convex surface, in the erect posture of the body, being directed upwards and forwards, and the concave downwards and backwards. The broad border is posterior and superior, and the thin margin anterior and inferior. If the trunk be inclined forwards the free edge of the liver may be felt, extending below the margin of the thorax.

It is in *relation* by its *convex surface*, superiorly with the diaphragm, which separates it from the under surface of the right lung and from the heart; anteriorly with the diaphragm and transversalis muscle, and with the sheath of the rectus and linea alba at the epigastrium; and on the right side with the diaphragm and transversalis muscle, which are interposed between it and the seven or eight lower ribs. Its *inferior* or *concave surface* is in relation with the anterior aspect of the stomach, the ascending portion of the duodenum, the transverse colon, the right supra-renal capsule, and the right kidney, and sometimes by its left extremity with the upper end of the spleen. The *posterior border* rests against the diaphragm, which intervenes between it and the vertebral column, and is in contact with the inferior vena cava, œsophagus, and right pneumogastric nerve. The *anterior border* is free and in relation with the transversalis muscle, which separates it from the cartilages of the lower ribs, with the round ligament at the notch, and with the sheath of the rectus and linea alba at the epigastrium.

The liver is *retained in its place* by duplicatures of peritoneum which pass between its convex surface and posterior border and the diaphragm, and by a fibrous cord which crosses from the linea alba to the inferior vena cava. These are the *ligaments* of the liver; they are five in number, the broad, the two lateral, the coronary, and the round ligament.

Fig. 32.



The upper or convex surface of the liver.

No 1, the right lobe; 2, the left lobe; 3, a part of the lobus Spigelii seen projecting beyond its posterior border; 4, 4, the anterior or narrow border; 5, the notch in the anterior border that gives passage to the round ligament 12; 6, 6, the posterior or rounded bord. r; 7, the broad ligament; 8, the left lateral ligament; 9, the right lateral ligament; 10, the point of separation of the layers of the right lateral ligament to inclose the oval space, 11, 11; 12, the round ligament; 13, the fundus of the gall-bladder projecting beyond the anterior margin of the liver. The notch upon the anterior margin corresponding with the gall-bladder is also seen; 14, the inferior vena cava emerging from the liver in the centre of the oval space of the coronary ligament. The small vessels seen ramifying upon the surface of the organ are superficial lymphatics.

The *broad ligament*, (*fig.* 32, 7) (falciform, longitudinal, l. latum, l. suspensorium hepatis) is an antero-posterior duplicature of peritoneum which extends from the notch on the anterior margin of the liver to the superior part of its posterior border. It is broad in front where it incloses the round ligament, and becomes narrow as it passes backwards; hence its synonym, *falciform*. It serves to connect the convex surface of the liver with the linea alba and diaphragm.

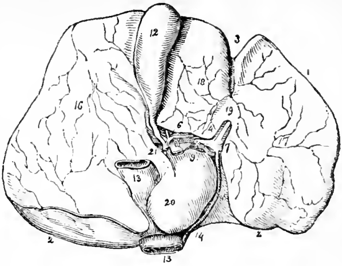
The *lateral ligaments* (*fig.* 32, 8, 9) (triangular) are two triangular folds of peritoneum which commence at each extremity of the posterior border of the liver and converge towards the termination of the broad ligament. They are broad near the extremities of the organ, and permit of a certain degree of motion in the right and left lobes, but become narrow as they approach the middle line. The two layers which compose the right lateral ligament separate as they pass inwards, and partly inclose an oval space (11, 11) of variable size, which is uncovered by peritoneum and in close contact with the diaphragm; the remainder of the space is bounded by the division of the layers of the broad and left lateral ligaments. The peritoneum surrounding this space, with the contained cellular tissue, which is large in quantity and connects the posterior border of the liver firmly with the right leaflet of the central tendon of the diaphragm, constitutes the *coronary ligament*. The inferior vena cava (14) emerges from the liver at about the middle of this space previously to its passage through the quadrilateral opening in the tendon of the diaphragm. The left lateral ligament, near to its extremity, advances a little upon the upper surface of the left lobe.

The *round ligament*, (*fig*. 33, 12) (ligamentum teres, umbilicale) is a rounded fibrous cord resulting from the obliteration of the umbilical vein of the fœtus. It is contained in the anterior margin of the broad ligament, and may be traced forwards along the linea alba to the umbilicus, and backwards through the notch in the anterior border of the liver and along the longitudinal fissure to the posterior border, where it is connected with the coats of the inferior vena cava.

Turning to the under surface of the liver we have to examine certain *fissures* which divide this aspect of the organ into lobes; the fissures are five in number; the longitudinal, the fissure for the ductus venosus, the transverse, the fissure for the gall-bladder, and the fissure for the vena cava.

The *longitudinal fissure*, (*fig*. 33, 4, 4) (sulcus longitudinalis, umbilicalis, horizontalis) extends, as it name implies, longitudinally across the concave surface of the liver from the notch on the free margin of the organ to its posterior border. At about two-thirds from the anterior border it is met by a short fissure, the transverse, which joins it at right angles. The longitudinal fissure up to this point is deep and is generally covered in by an arch of variable breadth (*pons hepatis*, *fig*. 33, 19) which connects the adjoining sides of the right and left lobes; beyond this point it is shallow and takes the name of *fissure for the ductus venosus* (5) from containing the fibrous cord into which the ductus venosus is converted after the cessation of fœtal circulation. The longitudinal fissure marks the division of the liver upon its under surface into a right and left lobe, and contains the fibrous cord of the round ligament, which is the degenerated umbilical vein of the fœtus. Opposite the extremity of the transverse fissure the fibrous cord is often partially dilated and communicates with the portal vein. This is an indication of the natural inosculation subsisting between these two vessels during intra-uterine existence.

Fig. 33.



The under or concave surface of the liver.

Nos. 1, 1, the anterior border; 2, 2, the posterior border; 3, the notch upon the anterior border; 4, 4, the longitudinal fissure containing the fibrous cord of the round ligament; 5, the fissure for the ductus venosus; 6, the transverse fissure; 7, the point of union of the three fissures, the longitudinal, the transverse, and that for the ductus venosus; 9, the portal vein in the transverse fissure, the hepatic artery, and the trunk of the ductus communis choledochus; 11, the cystic duct; 12, the gall-bladder; 13, 13, the inferior vena cava passing through its fissure; 14, the cord of the ductus venosus, joining the inferior cava as that vessel emerges from the substance of the liver; 15, part of the oval space on the posterior border of the liver; 16, the right lobe; 17, the left lobe; 18, the lobulus quadratus; 19, the pons hepatis; 20, the lobus Spigelii; 21, the lobus caudatus.

The *transverse fissure* (*fig*. 33, 6) (sulcus transversus, sulcus venæ portæ) is short and deep and about two inches in length; it commences near the middle of the under surface of the right lobe and passes transversely inwards to join the longitudinal fissure. It is the hilus of admission to the vessels of the liver, and gives passage to the hepatic artery, portal vein, and hepatic ducts, as well as to the lymphatics and nerves. The transverse fissure is bounded before and behind by the elevated borders of the lobus quadratus and lobus Spigelii. These lobes were named by the older anatomists the portal eminences, and were considered as the pillars which flanked the entrance to this great portal of the liver.

The *fissure* or rather the *fossa for the gall-bladder* is the shallow angular depression which lodges the biliary sac. It is broad in front and generally marked by a notch upon the anterior border of the liver, and narrows as it passes backwards. It is situated in the right lobe and runs parallel with the longitudinal fissure, while posteriorly it opens into the commencement of the transverse fissure.

The *fissure for the vena cava* (*fig*. 33) is situated in the same longitudinal line with the preceding, but upon the posterior border of the liver. It commences at the under surface of the organ and terminates upon the upper part of the posterior border at about the middle of the oval space inclosed by the coronary ligament. This fissure is always very deep and surrounds the vena cava for two-thirds or three-fourths of its cylinder. Sometimes it is converted into a canal by a thin layer which is stretched across it from the lobus Spigelii to the contiguous border of the right lobe. The hepatic veins pour their blood into this portion of the vena cava.

These five fissures taken collectively, namely, the longitudinal fissure and fissure for the ductus venosus on the left, the fissures for the gall-bladder and vena cava on the right, with the transverse fissure passing between them, are represented by Meckel as resembling the letter H, whereof the transverse bar is placed nearer to the posterior than to the anterior extremity. Viewing them in this way the two anterior branches are, the longitudinal fissure on the left and the fossa for the gall-bladder on the right; and the two posterior are, the fissure for the ductus venosus on the left, and the fissure for the vena cava on the right.

The existence of these five fissures upon the under surface of the liver causes its division into as many portions, which are named lobes, viz. the right, the left, the lobus quadratus, the lobus Spigelii, and the lobus caudatus.

The *right lobe*, (*fig.* 32, 1, *fig.* 33, 16,) (lobus major) is the largest division of the liver, and forms the whole of the bulky right extremity of the organ. It is convex upon its upper surface and irregularly concave below; at its right extremity and behind it is thick and rounded, and thin and sharp in front. It is separated from the left lobe on its convex surface by the broad ligament; beneath by the longitudinal fissure and fissure for the ductus venosus, and in front by the notch on the free margin of the liver. The transverse fissure and the fissures for the vena cava and gall-bladder are situated on the under surface of this lobe and serve to limit the boundaries of the three minor lobes; the lobus quadratus, Spigelii, and caudatus. Upon this surface it is marked by three depressions, one in front, of large size, for the right extremity of the transverse colon, and two behind, one for the right supra-renal capsule and another for the right kidney.

The *left lobe* (*fig.* 32, 2, *fig.* 33, 17,) (lobus minor) is four or six times smaller than the right; flattened in form, and thinned towards its circumference into a sharp margin. It is divided from the right lobe by the broad ligament above, by the notch in the anterior margin of the liver in front, and by the longitudinal fissure and fissure for the ductus venosus below. Superiorly it is convex and in relation with the diaphragm, to which it is connected by the left lateral ligament, and inferiorly it is concave, and presents a broad and shallow depression which rests upon the anterior surface of the stomach. By its extremity it sometimes touches the spleen, and by its posterior border corresponds with the termination of the œsophagus and with the right pneumogastric nerve.

The *lobus quadratus* (*fig.* 33, 18,) (anterior portal eminence) is a quadrilateral and slightly elevated division situated upon the under surface of the right lobe near to the middle line of the liver. It is bounded anteriorly by the free margin of the organ, posteriorly by the transverse fissure, to the left by the longitudinal fissure, and on the right by the fossa for the gall-bladder.

The *lobus Spigelii* (*fig.* 33, 20,) (posterior portal eminence) is a prominent conical lobe, smaller than the preceding, and situated near the posterior border of the liver, behind the two layers of the lesser omentum. Its base is triangular, and bounded in front by the transverse fissure; on the left side by the fissure for the ductus venosus, and on the right by the fissure for the vena cava and lobus caudatus, which last connects it with the under surface of the right lobe. By its anterior border it is in relation with the portal vein, by its left border with the fibrous cord of the ductus venosus, and by the right with the vena cava. Its posterior extremity is received into the angle of communication between the fibrous cord of the ductus venosus and the vena cava.

The *lobus caudatus* (*fig.* 33, 21,) is a tail-like appendage to the lobus Spigelii. It is extremely diversified in form, being sometimes well developed and a distinct lobe; at other times a mere vestige recognisible only to the eye of the experienced anatomist. Sometimes it is a slight ridge, merging into the surface of the liver on either side, and at other times is marked by a fissure on one side or even on both. Ordinarily it is an angular projection two or three inches in length, commencing by a narrow isthmus from the lobus Spigelii, passing obliquely outwards and forwards by the side of the gall-bladder, and subsiding at its extremity into the surface of the right lobe. The depression on the under surface of the right lobe, in front of this process, is for the reception of the curve of the ascending colon, and the posterior depressions for the right supra-renal capsule and right kidney.

The *coverings* of the liver are twofold, a serous investment, which is obtained from the peritoneum, and a proper fibrous capsule derived from the capsule of Glisson. The *peritoneum* encloses the whole of the liver with the exception of that part of the posterior border which constitutes the oval space (*fig.* 32, 11, *fig.* 33, 15,) and is surrounded by the coronary ligament, of the fossa for the gall-bladder, the fissure for the vena cava, and the transverse fissure. The *proper capsule* is most apparent upon those parts of the organ which are left uncovered by the peritoneum, particularly on the oval space upon its posterior border.

The *color* of the liver varies considerably, both with the period of life and with the greater or smaller proportion of blood or bile contained within its vessels. Thus in infancy it presents a light red colour, which deepens into a reddish brown in the adult, and increases in depth of shade with the age of the subject. If the individual have died from hæmorrhage, the liver appears bleached and presents a yellowish grey tint; if from general congestion, it may assume a chocolate or purplish brown or a slate colour, and if from obstruction to the bile-ducts, a variable shade of yellow. Its *texture* is firm and dense, but extremely fragile, the fracture presenting a granular appearance.

The *dimensions* of the liver are very considerable, as may be inferred by recollecting that this is the largest organ in the body. Through the longest diameter from the extremity of the right to the edge of the left lobe, it measures about twelve inches; from before backwards, through the transverse diameter of the right lobe, about seven inches, and through the thickest part of the right lobe, in a vertical direction, about four inches. These measurements, however, can only be received as an approximation to the average, for the size of the organ varies in different individuals; thus it is larger in males than in females, and is more bulky in persons of sedentary habits than in those who are robust and active. Its *weight* is about five pounds; its relative weight to the entire body, as 1 to 36; and the *specific gravity* one half heavier than water.

Chemical analysis of the human liver has shewn that in 100 parts, there are, of

Water 61.79
Solid matters 38.21

Of 100 parts of the solid matters,

71.18 are soluble in water, hot or cold, or alcohol; and consist of, osmazome, stearine, elaine, resin, oleic and margaric acids, gelatine, and salivine.

28.72 are insoluble.

2.034 are salts; viz. chloruret, phosphate of potash, phosphate of lime, and oxide of iron.

Bullocks' liver, analysed by Braconnot, is, according to Berzelius, analogous to the preceding, the differences being dependent solely upon a difference of manipulation. 100 parts contain,

55.50 water.
44.50 solid matters, composed of,
Vessels and membranes ..18.94
Soluble matters 25.56

100 parts of the pulp of liver contained,

58.64 water.
20.19 dry albumen.
6.07 matter very soluble in water; slightly in alcohol; containing little nitrogen.
3.89 fat.
0.64 chloruret of potash.
0.47 phosphate of lime containing iron.
0.10 salt of potash combined with a combustible acid.

Varieties in the liver may be referred to one of two heads—varieties in form, and varieties in position.

Varieties in form occasionally occur, but they are more rare in the liver than in almost any other organ of the body. I have seen the left lobe so small as to appear but a mere appendage to the right, being connected to it only by a thin and narrow isthmus. Cruveilhier records an instance in which the left lobe was attached to the right merely by a vascular pedicle about half an inch in length; the extremity of the lobe being adherent to the upper part of the spleen. Deep and narrow grooves are occasionally seen upon the convex surface of the right lobe running in an antero-posterior direction; they correspond with projecting fasciculi of the diaphragm, and occur generally in women who have laced tightly. This surface is also marked frequently in females with deep channels, which are formed by the pressure of the ribs, and are also the result of tight lacing. The liver is sometimes constricted in the middle from this cause, and a dense fibrous band, produced by thickening of the fibrous capsule, extends around it like a belt. The lobes are occasionally divided by deep fissures into several additional lobes; the liver in this case presents a character which is normal amongst the lower animals. In a few instances the fossa for the gall-bladder has been found excavated so deeply as to render the fundus of the sac apparent through an opening on the upper surface of the liver, a peculiarity which is also normal amongst some of the lower tribes of animals.

Varieties of position are more frequent than those of diversity of form. During utero-gestation the liver is usually pressed considerably above its ordinary plane, so as to impede more or less the action of the diaphragm and produce embarrassed respiration. In an extremely fat subject I once saw the diaphragm raised by the liver to a level with the fourth intercostal space, measured near to the sternum. In its natural position the thin margin of the liver scarcely reaches the border of the thorax, but in women who have laced tightly during youth nothing is more common than to find this edge forced several inches below the base of the thorax, and altered in its form. In these cases the direction of the aspects of the organ are likewise changed; the convex surface looks directly forwards, instead of upwards and forwards, and lies in contact with the abdominal parietes. The concave surface is directed backwards in place of downwards and backwards, and the posterior border is forced upwards. In a sketch from the subject, now before me, the greater part of the convex surface of the organ is in contact with the abdominal parietes, and the free margin extends into the umbilical and lumbar regions. In another sketch, as a result of the enormous magnitude of the stomach from the same cause, the liver is raised almost perpendicularly, the extremity of the left lobe being in contact with the diaphragm, and the right lobe in the right iliac fossa. A part of the liver has been found in the sac* of inguinal and umbilical hernia. Various peculiar appearances are observed in the liver of the fœtus arising from arrest of development. Thus, for instance, the entire organ, or a part of it, may be situated in the chest, or from absence of development of the abdominal parietes the liver may form part of

* Gunzius de Herniis, in Portal's Anatomie Médicale.

an exabdominal tumour, and be uncovered excepting by the membranes of the ovum. But the most interesting and unexplained form of altered position is that in which the whole of the viscera of the body are transposed, and the liver becomes placed on the left instead of the right side. These cases are generally perfect, and the peculiarity does not seem to interfere with the life or functions of the subject. The liver presents its natural form and size, and with the simple exception of left for right, precisely the same relations. The aorta, of course, occupies the right side, and the venæ cavæ the left, while the stomach is transferred to the right. Sir Astley Cooper has preserved the viscera of an adult who was the subject of this transposition. And a few years since I had the opportunity of examining a similar case in the body of Smithers, a man who was executed for committing arson accompanied with loss of life in Oxford-street. The viscera of this man were perfectly healthy, the liver finely formed, and the general fabric robust.

The *gall-bladder* (*fig*. 33, 12,) (cystis fellea) is a membranous sac of a pyriform shape, situated in the shallow fossa upon the under surface of the right lobe, and lying parallel with the longitudinal fissure. For convenience of description it has been customary to divide it into a body, fundus, and neck (cervix), although no precise mark of division subsists between these parts. The *body* is the middle portion; the *fundus* the expanded extremity, which approaches the notch in the free border of the liver, and frequently extends beyond it; and the *neck* the narrow and tapering portion of the sac which enters the right extremity of the transverse fissure and forms the cystic duct.

The sac is in *relation* by its upper surface with the substance of the liver, and by the under part with the pylorus and ascending duodenum. The fundus corresponds with the right border of the rectus muscle, and may be felt in that situation when filled with gall-stones.

The *coats* of the gall-bladder are three:—1. an external or serous covering derived from the peritoneum, which covers all that portion of the sac which is not in contact with the substance of the liver. The gall-bladder is sometimes completely surrounded by the peritoneum, and hangs loosely connected with the liver by a duplicature of that membrane. 2. A fibrous layer* (nervous) composed of cellulo-fibrous tissue intermingled with tendinous fibres; and, 3. a mucous coat which lines the interior of the sac, and is continuous through the cystic and hepatic ducts with the mucous lining of the biliary structure of the liver, and through the ductus communis choledochus with the mucous membrane of the duodenum and alimentary canal. The internal surface of the mucous layer is raised into innumerable small ridges and folds (rugæ) by the ramifications of the cystic artery and its capillaries, which give to it a peculiarly reticulated appearance, and the interspaces of the rugæ are depressed into numerous small muciparous follicles. In the neck of the sac the mucous membrane is produced into from six to twelve small folds, forming a kind of spiral valve by means of which the bile is regulated in its descent into the duodenum, and assisted in its entrance into the gall-bladder. The existence of this peculiar valvular apparatus gives to the neck of the gall-bladder a sacculated appearance. The mucous membrane is but loosely connected with the fibrous coat, and the cystic artery with its branches ramify between them.

The excretory duct of the gall-bladder is the *cystic*, (*fig*. 33, 11); it is about an inch and a half in length, and in diameter about equal to the cylinder of a crow's quill. It is generally somewhat tortuous in its course, and appears sacculated from the continuation into it of the spiral valve. Upon entering the transverse fissure it unites with the excretory duct of the liver, the ***hepatic duct***, and the junction of the two constitutes the ductus communis choledochus. The *ductus communis choledochus*, about three inches in length, descends through the right border of the lesser omentum, lying in front of the portal vein, and to the right of the hepatic artery, and opens into the duodenum by passing for some distance obliquely between its coats. It is united to the other vessels in its course by the cellular tissue of Glisson's capsule, and near to its termination is considerably constricted.

The excretory ducts of the liver and gall-bladder have three coats, an external or cellular coat, a middle or fibrous, and an internal mucous. A question exists among physiologists as to the probable muscularity of the middle coat in man; it is undoubtedly contractile, and in some few instances of obstruction has presented an appearance very closely resembling muscular fibres. Cruveilhier thinks the structure analogous to the dartos. In some animals, as in the horse and dog, this coat is clearly muscular.

Varieties in the gall-bladder.—The sac is sometimes enormously dilated without any apparent obstruction in its ducts. Occasionally in acephalous and anencephalous fœtuses it is altogether absent. In a preparation now before me of the liver of a fœtus at the full period, which lived for several hours after birth, and which presented, in anatomical structure, several peculiarities dependent upon arrest of development, the most careful dissection has failed to discover the slightest indication of gall-bladder. Among the lower mammalia, as in cats, a double or accessory gall-bladder is by no means uncommon. Kiernan has observed several instances of this variety. I myself have seen two, and have one at present before me. In the kinkaju an accessory gall-bladder is the normal character, and in the liver of a small animal preserved by Hunter in the Museum of the College of Surgeons, there are three gall-bladders.

Structure of the liver.—The liver is composed of lobules, of a connecting medium

* In the ox, according to Monro, this coat is distinctly muscular.

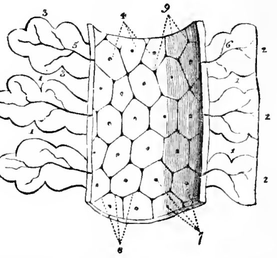
called Glisson's capsule, of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics and nerves. For an accurate knowledge of these different structures, anatomy is indebted to the labours of Mr. Kiernan, to whose paper on "The Anatomy and Physiology of the Liver," contained in the Philosophical Transactions for 1833, I shall have constant occasion to refer.

The small bodies (lobules, acini, corpuscula, glandular grains, granulations) of which the liver is composed were discovered by Wepfer in the liver of the pig, about two years previously to the appearance of Malpighi's celebrated work, "De Viscerum Structurâ Exercitatio Anatomica." Malpighi, unacquainted with Wepfer's discovery, examined and described these bodies, both in animals and in man, under the name of *lobules;* and the lobules he found to consist of smaller bodies, which he named *acini*. From some want of precision in Malpighi's descriptions, these two names have been confounded by the majority of succeeding anatomists; the term *lobules*, with its distinctive application, has been disregarded and forgotten, and the term *acini* has been applied to those minute bodies of which the liver appears to be formed when examined beneath the microscope with a moderate power, —the acini of Malpighi. So great, indeed, is the confusion of terms even in 1838, that we find a justly celebrated authority in minute anatomy, Müller, in speaking of Kiernan's discovery, using the following words. "He" (Kiernan) "describes the lobules of the liver (which by other anatomists are termed acini)," and further on he observes: "his description of their form is indeed similar to that which we have given above of the acini of the macerated liver of the polar bear." Now, setting aside the anachronism of discovery contained in the above quotation, which, as it appears to me, should have been, *our description of the acini of the polar bear is similar to his description of the form of the lobules,* inasmuch as Kiernan's discovery was published in 1833, and Müller's description of the macerated liver of the polar bear in 1835, I cannot but feel somewhat surprised in observing that Müller draws no line of distinction between the lobules and their supposed constituents the acini. Nay, that he would seem to imply that all anatomists were acquainted with the lobules, but that they assigned to them a different name. To prove that this is not the case, I quote a passage from his work upon the glands, published in 1830, in which he expresses himself unable to distinguish the elementary structure of the liver either in man or in numerous other mammalia, for he says, "In homine, ut in plurimis mammalibus, in hepatis superficie certa quædam particularum elementarium sive *acinorum* conformatio *conspici non potest*." Now the question to be decided, is the meaning which he assigns in this quotation to the word *acinorum;* does he mean by that word the lobules or the acini of Malpighi? The solution is simple; we have it in his own words, and exhibited in a figure in which his peculiar views of the anatomy of the organ are clearly illustrated. In this figure, (*fig.* 217, page 485,) he says, "Observantur fines ductuum biliferorum elongati, seu cylindriformes acini, in figuris ramosis et foliatis variè dispositi." So that the acini of Müller in 1830 are the terminations of the biliferous ducts, corresponding therefore with the acini of Malpighi, and the lobular biliary plexus of Kiernan. In 1835, as instanced in the "macerated liver of the polar bear," the acini of Müller are the lobules of Malpighi and Kiernan.

Now seeing this indecision of opinion upon a subject of so great importance in relation to the proper understanding of the minute anatomy of the liver, I have deemed it my duty, in the service of anatomy, to place before my readers this cursory sketch of the history of the anatomy of the organ, and to establish the meaning of the terms I shall have occasion to use in describing its intimate structure. By the word *lobules* I shall mean, not the acini of anatomists, "which are anything or everything or nothing as the case may be," but the lobules of Malpighi and of Kiernan;—by the word *acini* I shall indicate the smaller bodies of which the lobules appear to be composed (acini of Malpighi and of all writers); but which have been shewn by Kiernan to be the meshes of a plexus of biliary ducts, the "lobular biliary plexus."

The *lobules* are small granular bodies of about the size of a millet-seed, of an irregular form, and presenting a number of rounded projecting processes upon their surface. When divided longitudinally (*fig.* 34) they have a foliated appearance, and transversely (*fig.* 35)

Fig. 34.

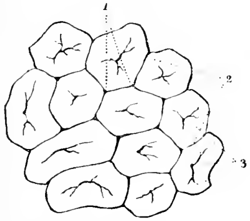


A longitudinal section of a sub-lobular vein.

Nos. 1, 1, longitudinal sections of lobules, presenting a foliated appearance. 2, 2, superficial lobules terminating by a flat extremity upon the surface of the liver; 3, 3, the capsular surface of a lobule; 4, the bases of the lobules seen through the coats of the vein and forming the canal in which the sub-lobular vein is contained; 5, the intra-lobular vein commencing by minute venules at a short distance from the capsular surface of the lobule; 6, the intra-lobular vein of a superficial lobule commencing directly from the surface; 7, the openings of the intra-lobular veins which issue from the centre of the base of each lobule; 8, the interlobular fissures seen through the coats of the sub-lobular vein; 9, interlobular spaces.

an irregularly pentagonal or hexagonal outline with sharp or rounded angles in proportion to the smaller or greater quantity of Glisson's capsule contained within the liver. Each lobule is divided upon its exterior into a base and a capsular surface. The *base* (*fig.* 34, 4) corresponds with one extremity of the lobule, is flattened and rests upon an hepatic vein, which is thence named *sub-lobular*. The *capsular surface* (*fig.* 34, 3, 3) includes the rest of the periphery of the lobule, and has received its designation from being inclosed in a cellular capsule derived from the capsule of Glisson. In the centre of each lobule is a small vein, the *intra-lobular* (*fig.* 34, 5, 6, *fig.* 35, 3) which is formed by the convergence of six or eight minute venules from the rounded processes situated upon the surface of the lobule. The intra-lobular vein thus constituted takes its course through the centre of the longitudinal axis of the lobule, pierces the middle of its base, and opens into the sub-lobular vein. The circumference of the lobule with the exception of its base, which is always closely attached to a sub-lobular vein, is connected by means of its cellular capsule with the capsular surfaces of surrounding lobules. The cellular interval between the lobules is the *interlobular fissure* (*fig.* 34, 8, *fig.* 35, 2), and the angular interstices formed by the apposition of several lobules are the *interlobular spaces* (*fig.* 34, 9, *fig.* 35, 1).

Fig. 35.



Angular lobules in a state of anæmia. From Kiernan's paper.

No. 1, interlobular spaces, containing the larger interlobular branches of the portal vein, hepatic artery and duct; 2, interlobular fissures; 3, intra-lobular veins formed by minute venules which converge towards the centre of the lobules.

The lobules present considerable variety of form dependent upon their situation and upon the manner in which they are examined. For instance, the section of a lobule divided transversely has an irregularly pentagonal or hexagonal figure, and longitudinally a foliated appearance. The lobules of the centre of the liver are angular and smaller than those of the surface, on account of the pressure to which, from their position, they are submitted by surrounding lobules. They are also more angular in some animals than in man. The surface of the liver of the cat, in which the portal vein is injected, has a beautiful reticulated appearance produced by angular meshes of an hexagonal figure; the hexagonal outline being formed by the interlobular fissures, reddened by the injection in the minute branches of the portal vein, and the included area by the lobule viewed upon its transverse diameter. In a section of the liver made from the free margin to the posterior border in the direction of the hepatic veins, the lobules are found to be larger than in a section made transversely to those vessels. The lobules of the exterior, particularly on the concave side and posterior border, are for the same reason larger from lying obliquely to the surface and corresponding in direction with the course of the sub-lobular veins. They are also more rounded from the absence of compression by surrounding lobules. But one appearance described by Kiernan is peculiarly characteristic of the lobules which form the surface of the liver, the *superficial lobules*. The word *surface* in this instance does not refer simply to the periphery of the organ, but also to the various canals channelled through its interior for the passage of the portal vein, hepatic ducts, and hepatic artery, and also for the main trunks of the hepatic vein, " all these canals being" as it were " tubular inflections inwards of the superficies of the liver." The superficial lobules (*fig.* 34, 2, *fig.* 35) are not terminated by a rounded extremity like those of the centre, but are flat and apparently incomplete, and as though cut across by a transverse incision. This peculiar form gives to the anatomist a natural surface which affords all the advantages for observation of a transverse section, and enables him to detect by external examination the relative condition of both the central portion and surface of the lobule. In these lobules also the intra-lobular hepatic vein, instead of being entirely concealed within the lobule, commences directly from the flat surface. A knowledge of this structure, says Kiernan, "enables us in injecting the hepatic veins to limit the injection to this system of vessels, which is effected by withdrawing the syringe when the injection appears in minute points upon the surface of the liver." Occasionally double lobules, or lobules having two intra-lobular veins, are seen upon the surface.

" Each lobule," according to Kiernan, "is composed of a plexus of biliary ducts, of a venous plexus formed by branches of the portal vein, of a branch (intra-lobular) of an hepatic vein, and of minute arteries; nerves and absorbents, it is to be presumed, also enter into their formation, but cannot be traced into them." " Examined with the microscope, a lobule is apparently composed of numerous minute bodies of a yellowish colour, and of various forms, connected with each other by vessels. These minute bodies are the acini of Malpighi." " If an uninjected lobule be examined and contrasted with an injected lobule, it will be found that the acini of Malpighi in the former are identical with the injected lobular plexus of the latter, and the bloodvessels in both will be easily distinguished from the ducts."

Glisson's capsule is the web of cellular tissue which envelopes the hepatic artery, portal vein, and ductus communis choledochus during their passage through the right border of the lesser omentum, and which accompanies them along the portal canals and interlobular fissures to their ultimate distribution in the substance of the lobules. It forms for each of the lobules a distinct capsule which invests it on all sides with the exception of its base, and is then expanded over the whole of the exterior of the organ, constituting the *proper capsule* of the liver. Glisson's capsule serves to maintain the portal vein, hepatic artery, and hepatic ducts in connection with each other, and attaches them also to the surface of the portal canals; it connects the trunks of the hepatic veins to the surface of the canals in which they run; it supports the lobules and binds them together, and by its exterior expansion it invests and protects the entire organ. But Glisson's capsule, observes Kiernan, " is not mere cellular tissue; it is to the liver what the pia mater is to the brain; it is a cellulo-vascular membrane, in which the vessels divide and subdivide to an extreme degree of minuteness; which lines the portal canals, forming sheaths for the larger vessels contained in them, and a web in which the smaller vessels ramify; which enters the interlobular fissures, and with the vessels forms the capsules of the lobules, and which finally enters the lobules, and with the bloodvessels expands itself over the secreting biliary ducts. Hence arises a natural division of the capsule into three portions, a vaginal, an interlobular, and a lobular portion."

The *vaginal portion of the capsule* is loose and abundant; it occupies the portal canals and incloses the portal vein, hepatic duct, and hepatic artery. In the larger canals (*fig.* 36, 8,) it completely surrounds these vessels, but in the smaller ones (*fig.* 37,) is situated only on that side of the portal vein upon which the duct and artery are placed, the opposite side of the vein being in contact with the capsular surfaces of the lobules. It constitutes a medium for the ramification of the vaginal plexus formed by the vein, artery, and duct, previously to their entrance into the cellular interval of the interlobular fissures.

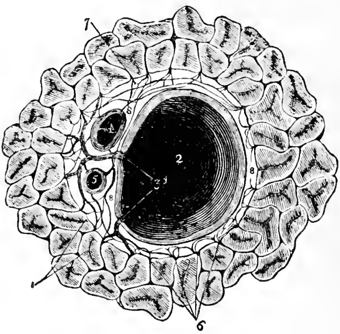
The *interlobular portion* forms the cellular capsule for each of the lobules and the bond of union between their contiguous surfaces. It supports the plexiform ramifications of the portal vein, hepatic artery, and duct, and is the medium of vascular communication between all the lobules of the liver.

The *lobular portion* forms sheaths for the minute vessels which enter the lobules, and a cellular parenchyma for the substance of those bodies.

The *portal vein* is formed by the union of the venous trunks which return the blood from the chylopoietic viscera, viz., the superior and inferior mesenteric, the splenic, and gastric veins. Commencing behind the pancreas where all these veins converge, the portal trunk ascends along the right border of the lesser omentum, lying behind the hepatic artery and ductus communis choledochus to the transverse fissure. At the transverse fissure it bifurcates into two trunks which enter the right and left lobes, and divide and subdivide as they take their course through the portal canals, until they are ultimately lost in the substance of the lobules. The branches of the portal vein are accompanied throughout their course by branches of the hepatic duct and hepatic artery, and they are inclosed and connected to the capsular surfaces of the lobules forming the portal canals, by Glisson's capsule. The branches of the portal vein are divisible into vaginal, interlobular, and lobular.

The *vaginal branches* (*fig* 36, 3, *fig.* 38, *f*) are the small veins which are given off by the portal trunks during their passage through the portal canals, and which are intended to convey

Fig. 36.

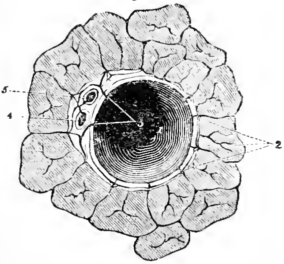


A transverse section of a large portal canal and its vessels. The lobules are in a state of general congestion, their central portions being more congested than their marginal portions. — From Kiernan's paper.

No. 1, Superficial lobules forming the parietes of the canal. In some the intra-lobular vein does not extend to the surface of the canal; this appearance depends upon the direction in which the incision is made. 2, The portal vein. 3, Vaginal branches arising from the vein and dividing into interlobular branches which enter the interlobular spaces. 4, Hepatic duct. It is seen to give off vaginal branches which divide into interlobular ducts, the latter enter the interlobular spaces. 5, The hepatic artery; it is seen giving off vaginal branches which divide into interlobular branches, and the latter enter the spaces with the branches of the portal vein and hepatic duct. 6, Three interlobular vessels, a duct, vein, and artery, entering each interlobular space. 7, A part of the vaginal plexus. 8, 8, Glisson's capsule, which completely surrounds the vessels.

their blood into the substance of the lobules. In the cellular sheath of Glisson's capsule which surrounds the portal vein, they inosculate freely with each other and form, together with the vaginal branches of the duct and artery, a vascular plexus, named from its situation the *vaginal plexus*. This vaginal plexus establishes a communication between the vaginal veins throughout the portal canals, and serves to equalise the supply of blood to the lobules. Opposite each interlobular space an interlobular vein is given off, which enters between the lobules and ramifies in the interlobular fissures. In the larger portal canals (*fig.* 36,) the vaginal plexus completely surrounds the portal vein, hepatic duct and hepatic artery, and the interlobular spaces are supplied solely with branches which are derived from its ramifications. But in the smaller portal canals (*fig.* 37, *fig.* 38) the capsule of Glisson, upon which the plexus chiefly depends, is

Fig. 37.



A transverse section of a small portal canal and its vessels. The lobules are in a state of general congestion. From Kiernan's paper.

No. 1, The portal vein; the greater part of its cylinder is in contact with the portal canal. 2, Interlobular branches of the vein entering directly the interlobular spaces, with branches of the artery and duct, without ramifying in the canal. 3, Two vaginal branches arising from the vein, and forming a vaginal plexus on that side of the vein, which is separated from the canal by Glisson's capsule. From the plexus the interlobular branches arise. 4, The hepatic duct giving off vaginal branches. 5, The artery giving off vaginal branches. Glisson's capsule is situated on one side only of the canal.

Fig. 38.

a, Portions of the canal from which the vein is removed to show that it is formed by lobules which present the same appearance with those upon the external surface of the liver. *b*, The side of the portal vein which is in contact with the canal. *c*, The side of the vein which is separated from the canal by the hepatic artery and duct, by the Glisson's capsule surrounding them, and by the vaginal plexus. *d*, The internal surface of the portal vein, through which is seen the outline of the lobules, and the openings of the interlobular veins which correspond with the interlobular spaces. Upon the opposite side (*c*), the portal vein being separated from the portal canal there are no interlobular veins. *e*, The openings of smaller portal veins. *f*, Vaginal veins giving off branches in the portal canal and forming a plexus. *g*, The hepatic artery giving off vaginal branches. *h*, The hepatic duct giving off vaginal branches.

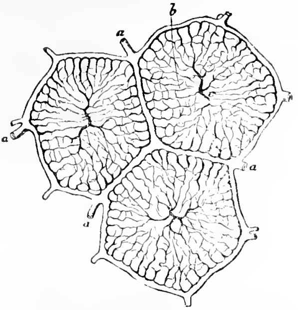
situated only upon that side of the vein, on which the duct and artery are placed, and the vaginal plexus consequently follows the same disposition. On the opposite side the portal vein being in contact with the lobules, gives off interlobular branches directly to the spaces. If the portal vein (*fig.* 38) be laid open in this situation, the form of the lobules bounded by the interlobular fissures will be distinctly apparent through its coats, and the openings of the interlobular veins will be found to correspond with the interlobular spaces.

The *interlobular veins* enter the intervals of the lobules through the interlobular spaces and divide into numerous minute branches, which ramify in the capsules of the lobules and then enter their substance. They cover with their ramifications the whole external surface of the lobules with the exception of their bases, and of those extremities of the superficial lobules which appear upon the surfaces of the liver. The interlobular veins communicate freely with each other and with the corresponding branches of adjoining lobules, and establish a general portal anastomosis of the freest kind throughout the entire liver. When the portal vein is well injected, these veins form a series of inosculations which surround all the lobules and give to the surface of the organ the appearance of a vascular network composed of irregularly pentagonal and hexagonal meshes. If the vein be only partially injected the interlobular vein in the interlobular space is alone filled, and the branches which it sends off into the neighbouring interlobular fissures not proceeding so far as to inosculate and form meshes, have a radiated appearance and resemble a number of minute stellæ; these are the *stellated vessels* of anatomists.

The *lobular veins* are derived from the interlobular veins; they form a plexus within the lobule, and converge from the circumference towards the centre, where they terminate in the minute branches of the intralobular vein. "This plexus, interposed between the interlobular portal veins and the intralobular hepatic vein, constitutes the venous part of the lobule, and may be called the *lobular venous plexus.*" (*fig.* 39). The irregular islets of the substance of the lobules seen between the meshes of this plexus by means of the microscope are the acini of Malpighi, and are shown by Kiernan to be portions of the lobular biliary plexus.

The portal vein collects the venous blood from the chylopoietic viscera, and then circulates it through the lobules; it likewise receives the venous blood which results from the distribution of the hepatic artery to the structures of the liver; these two sources of supply constitute the two origins of the portal vein, the *abdominal origin* and the *hepatic origin.*

Fig. 39.



Two lobules, in which the portal venous plexus is seen. After Kiernan.

a a, Interlobular veins. The appearance of venous circles formed by these veins is that which is afforded by a common lens; when examined with a higher power the interlobular fissure is seen to be filled by a vascular plexus. *b,* The lobular venous plexus. The circular and ovoid spaces seen between the branches of the plexuses are occupied by portions of the biliary plexus: they are the acini of Malpighi. *c,* The intralobular vein in the centre of each lobule, collecting the blood from the lobular venous plexus.

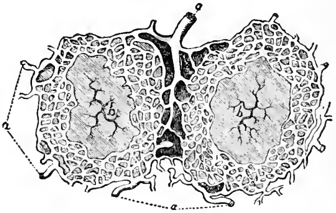
The *hepatic duct* bifurcates in the transverse fissure into two branches, which enter the right and left lobes of the liver and subdivide into smaller branches, and the smaller branches accompany the divisions of the portal vein and hepatic artery through the portal canals to their ultimate distribution in the lobules. The branches of the hepatic duct, like those of the portal vein, are divisible into the vaginal, interlobular, and lobular ducts.

The *vaginal ducts* pass transversely through the capsule of Glisson, by which they are enveloped in common with the portal vein and hepatic artery, and divide into numerous small branches which assist in forming the *vaginal plexus.* From the plexus of ducts two kinds of branches are given off, the *interlobular,* which run along the margins of the interlobular fissures and enter the interlobular spaces to be distributed upon the capsular surfaces of the lobules; and the *lobular,* which enter the substance of those lobules which form the parietes of the portal canals. In the smaller portal canals the vaginal branches and plexus are situated only on the portal side of the canal, the interlobular branches, on the side nearest the duct, passing directly into the interlobular spaces. "The transverse branches and those which arise immediately from them do not anastomose with each other, but the smaller branches sometimes appear to do so; I cannot, however," says Kiernan, "from dissection, affirm that they do, for those which appear to anastomose are exceedingly small vessels and meet each other at the spaces, hence it is difficult to ascertain whether they really anastomose or enter the spaces together without anastomosing."

The *interlobular ducts* ramify upon the capsular surface of the lobules with the branches of the portal vein and hepatic artery. Kiernan finds these ducts to communicate freely with each other, for he says, "If the left hepatic duct be injected with size or mercury, the injection will return by the right duct without extravasation and without passing into other vessels, and the injection will be found in the interlobular and vaginal ducts as well as in the trunks. This communication between the two ducts does not take place like that which exists between the right and left arteries through the medium of the vaginal branches of the transverse fissure, the injection being found in interlobular branches arising from the right duct. From this experiment, which I have frequently repeated with the same result, it appears that the right and left duct anastomose with each other through the medium of the interlobular ducts. This experiment does not always succeed, which probably arises from the quantity of bile contained in the ducts."

The *lobular ducts* entering the lobule by its circumference divide and subdivide into minute branches which anastomose with each other and form a "reticulated plexus," the *lobular biliary plexus* (*fig.* 40). This plexus constitutes the principal part of the substance of the lobule, and seen through the meshes of the portal venous plexus, gives rise to the appearance of acini or of cœcal terminations of ducts. The ultimate terminations of the ducts have not yet been seen; they are imagined by Müller to end in "short pannicle-like tufts closely interwoven together," and he supports his opinion by citing the circumstance of the ducts in the embryo of the fowl and larva of

Fig. 40.



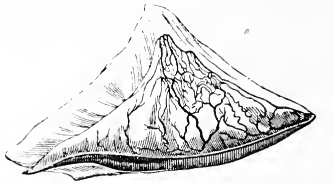
Two lobules in which the lobular biliary plexus is shewn. After Kiernan.

a a, Interlobular ducts giving off branches which form the plexus within the lobules. The central portion of the lobules is uninjected. *b b,* The ramifications of the intralobular veins. With regard to this figure Kiernan observes, "No such view of the ducts as that represented in this figure can be obtained in the liver. The interlobular ducts are in the figure seen anastomosing with each other. I have never seen these anastomoses, but I have seen the anastomoses of the ducts in the left lateral ligament, and from the results of experiments related in this paper, I believe the interlobular ducts anastomose. I have never injected the lobular biliary plexuses to the extent represented in the figure."

the frog ending in twig-like terminations. Kiernan inclines to the opinion that they terminate in loops, although he says nothing which could lead us to suppose that he rejects the possibility of their terminations being cœcal. Both authors agree that they end by closed extremities. It is this plexus which constitutes the true glandular portion of the liver.

Müller, in reference to the terminations of the ducts in anastomosing plexuses, states, that the history of the development of the organ is opposed to the belief in the existence of anastomoses. Certainly, if we are to credit the principle which he himself has established for the development of glands, viz. that " however various the form of the elementary parts, all secreting glands without exception follow the same law of conformation," the same process must take place in all; and analogy would lead us to infer that a plexiform anastomosis would be the arrangement of the terminal ducts in so complicated a gland as the liver of the adult, whatsoever it may happen to be in the undeveloped organ of the embryo. That there is nothing irrational in this opinion we would turn for proof to another page of his Physiology, where he observes, " in the scorpion, as I have discovered, the tubes (of the testis) *anastomose*, forming loops." Again, he says, " Lauth has but once seen a seminal canal ending with a free extremity in the human testis. Krause has seen such free ends of the tubuli seminiferi frequently, and confirms the opinion of their terminating in that way as well as by anastomosis. Lauth attributes the circumstance of free extremities of the tubes being so seldom seen to their uniting with each other so as to form loops. He describes the division and reunion of the tubes to be so frequent that in a small portion which he spread out, and in which there were about forty-nine inches of tube, he found about fifteen anastomoses. It is, however, only towards their extremities that the seminal tubes anastomose thus freely. The discovery of the anastomoses of the seminal tubes is perfectly original." Krause observes the same fact also with regard to the uriniferous ducts. Now I would ask why, if the ducts of the seminal gland and uriniferous gland anastomose so freely, the ducts of the biliary gland should not do the same? And why, if the anastomoses of the seminal ducts be a discovery *so original*, the less easily demonstrable fact of the anastomoses of the biliary ducts, discovered by Kiernan, may not be equally original? I speak from laborious research upon this subject, and surely there cannot be a comparison between the difficulty of unravelling the simple ducts of the testis and the complicated and minute masses of the biliary ducts, an aggregation so intricate that Müller acknowledges it " difficult to decide the question." The above facts of the anastomoses of the seminal and uriniferous ducts would, in my mind, were other evidence wanting, be a circumstance powerfully aiding my belief in the anastomoses of the biliary ducts; but the subject is not without its proofs, and these, as it appears to me, from careful examination, incontestible. " The left lateral ligament," says Kiernan, " may be considered as a rudimental liver, in which this organ presents itself to our examination in its simplest form. From that edge of the liver connected to the ligament, numerous ducts emerge, which ramify between the two layers of peritoneum of which the ligament is composed." " These ducts, the smallest of which are very tortuous in their course, divide, subdivide, and anastomose with each other. They are sometimes exceedingly numerous, two or three of them in such cases being of considerable size; some of them, as Ferrein" (by whom they were discovered) " says, frequently extend to the diaphragm and ramify on its inferior surface. They sometimes extend only half way up the ligament, where they divide into branches, which forming arches (*fig.* 41,) return and descend towards the liver,

Fig. 41.



*The left lateral ligament, in which are seen the injected biliary ducts with their anastomoses. After Kiernan.**

anastomosing or being continuous with other ducts issuing from it. The spaces between the larger or excreting ducts are occupied by plexuses of minute or secreting ducts." " Branches of the portal and hepatic veins, with arteries and absorbents, also ramify in the ligament, which, including between its layers a plexus of secreting and excreting ducts, with bloodvessels ramifying on their parietes, admirably displays the structure of the liver." The same appearances are seen in the bands which sometimes arch over the vena cava and longitudinal fissure, when they are sufficiently thin.

The hepatic ducts are extremely vascular, and in a well-injected liver are always completely covered with the ramifications of the hepatic artery. The rugæ upon their internal surface are formed by large vessels, " arteries as well as veins," which are distributed beneath the mucous membrane. This membrane, seen beneath the microscope, appears plaited over every part of its surface by innumerable laminated papillæ of a semilunar form. The vessels distributed upon these papillæ consist of an artery which ascends upon each side of the lamina, and divides into a beautiful net-work of capillaries which are collected after their distribution into a small vein and returned to the portal vein. " It is," says Kiernan, " to the rupture of the delicate vessels forming these

* I have carefully examined this preparation and pledge myself to its accuracy.

papillæ that is to be attributed the facility with which Söemmering and other anatomists injected the ducts from the arteries and veins, and not to any direct communication between the vessels and the ducts."

The mucous lining of the ducts is provided with a considerable number of muciparous follicles which mingle their secretion with the bile during its passage along the excretory tubes. These follicles have been described by all anatomists as existing in the larger ducts, but they were not known to be present in the smaller branches until they were discovered and figured by Kiernan. In the larger ducts they are irregularly dispersed, but in the smaller tubes are found arranged in two longitudinal rows upon opposite sides of the ducts. Hence the vascularity of the hepatic ducts is intended to perform a higher function than the mere nutrition of those tubes; it provides an important secretion as an auxiliary to the composition of the bile.

The *hepatic artery* arises from the cœliac axis and ascends through the right border of the lesser omentum to the transverse fissure of the liver, where it bifurcates into two branches for the right and left lobes. The right and left hepatic arteries ramify in the portal canals, and give off branches which accompany each twig of the portal vein and hepatic duct. Their branches, like those of the vein and duct, are the vaginal, the interlobular, and the lobular.

The *vaginal arteries* arise from the hepatic arteries in the portal canals, and assist in forming the vaginal plexus in the capsule of Glisson, from which the interlobular branches are given off to accompany the interlobular portal veins and ducts. In the larger canals the plexus completely surrounds the portal vessels, but in the smaller canals the plexus is situated only on the side opposite to the cylinder of the artery, and in the tissue of Glisson's capsule. This vaginal plexus has the effect of supplying the lobules which are the most distant from the vessel to which they belong, as certainly, as those which are in immediate contact with its cylinder. The vaginal arteries anastomose so freely with each other, that if the hepatic artery of one side be injected, the injection will return by that of the opposite side.

The *interlobular arteries* enter the intervals of the lobules through the interlobular spaces and ramify upon the capsular surface of the lobules. They are distributed principally to the interlobular ducts, around which they form a vascular net-work. The question of the inosculation of these vessels is very difficult to decide by dissection on account of their extreme minuteness; but analogy would lead us to infer that they must communicate.

The *lobular arteries*, "exceedinuly minute and few in number," so as to be demonstrable with much difficulty in the structure of the lobules, enter the circumference of these bodies with the lobular ducts upon which they are distributed. They are the nutrient vessels of the lobules, and terminate in the lobular venous plexus formed by the portal vein.

The mode of distribution of the hepatic artery is a subject upon which some difference of opinion subsists between Müller and Kiernan. Kiernan states that the hepatic artery is distributed chiefly upon the coats of the ducts and gall-bladder, upon the coats of the other vessels to which it forms the vasa vasorum, and to the substance of the lobules. The ducts are highly vascular, and are abundantly supplied, the lobules sparingly, but "few" vessels, and those "exceedingly minute," being traceable into them. From the capillaries of the ducts and vessels, the blood having become venous during its circulation is returned into the portal vein, and thence conveyed onwards to the lobules, where it is distributed through the lobular venous plexus. The blood of the terminal lobular arteries also becomes venous in the substance of the lobules, and is likewise poured into the lobular venous plexus. So that, according to this author, the whole of the blood distributed through the hepatic artery is received by the portal vein, either in the course of that vessel, or at its termination in the lobular venous plexus, and therefore, that all the blood circulating through the plexus must necessarily be *venous*. He likewise affirms that no part of the blood of the artery is poured directly into the hepatic vein. "The intralobular veins," he says, "convey the blood from the lobular venous plexus, and not from the arteries." These views are the results of the evidence of numerous experimental injections. With regard to the vascularity of the lobules, he observes, "These bodies cannot be coloured with injection from the artery, even in the young subject; in the adult, after the most successful injection, when the arteries of the cellular capsule, those of the excreting ducts and gall-bladder, and the vasa vasorum are minutely injected, a few injected vessels only are detected entering the lobules. I have frequently tied the thoracic aorta in living animals, thereby cutting off all supply of blood from the abdominal viscera; and in these animals, when injected from the aorta below the ligature forty-eight hours after death, the integuments, the secreting portions of the kidneys, the spleen, pancreas, intestines, and pelvic viscera were coloured in a remarkable degree by the injection; on the surface of the liver a few vessels only could be discovered, this organ presenting a curious contrast with the surrounding coloured viscera. The gall-bladder and ducts were, however, equally well injected with the intestines; the vasa vasorum were also well injected." Perceiving in the progress of his experiments that the injection thrown into the artery passed freely into the portal vein by means of the capillary communication existing between these two vessels on the coats of the ducts, and through the vasa vasorum of the vessels, he imagined that the injected fluid might in this way be diverted from the lobules, and that this must be the cause of his want of success in filling the lobular arteries. To ascertain if such were the case, he injected the portal vein in the first instance with blue, and then the arteries with red. "On dissection, branches of the two sets of vessels were found in the coats of the vessels, and in those of the excreting ducts and gall-bladder; the lobules were coloured with the blue injection; the red was confined to their circumference, and appeared in points only. This experiment was varied by injecting the portal vein and its branches as far only as the entrance of the latter into the lobules, the lobules thus remaining uninjected. The injection propelled through the arteries had now free access to the uninjected lobules, and no exit by the injected portal vein; and the artery having no communication with the hepatic veins, the injection had no exit by these vessels: the lobules however were not better injected in this than in the preceding experiments. From these experiments I conclude, that the secreting part of the liver" "is supplied with arterial blood for nutrition only. As all the branches of the artery of which we can ascertain the termination, end in branches of the portal vein, it is probable that the lobular arteries terminate in the lobular venous plexuses formed by that vein, and not in the intralobular branches of the hepatic veins, which cannot be injected from the artery." Müller, who published upon this subject previously to the discoveries of Kiernan, and was therefore not aware of the exact distribution of the vessels, was deceived by this free communication between the hepatic artery and portal vein. He conceived, with the older anatomists, that the arterial blood was mixed with the venous blood of the vena portæ, in a capillary network, "vascula ultima reticulata," common to the three bloodvessels of the liver, the hepatic artery, portal vein and hepatic veins. Observing, moreover, in the injected preparations of Lieberkühn,* that the "vascula ultima reticulata," the lobular venous plexus of Kiernan, appeared as well filled when the injected fluid was forced into the hepatic artery, as when introduced through the portal or hepatic vein, he at once decided that the artery must pour its blood directly into this plexus. Hence he writes, "Vascula ultima reticulata sanguinem tam ab arteriis quam a venâ portarum accipere, venisque hepaticis reddere, ex hisce argumentis concludo: Post injectionem in arteriam hepaticam non minus quam in venam portarum aut venas hepaticas factam, eadem communia vasculorum minimorum retia replentur, quod ex injectionibus exsiccatis Lieberkühnianis, Berolini asservatis, facile quisquis sibi persuadebit." Having recourse himself to an extremely imperfect experiment, the injection of water into the hepatic artery, and finding that this fluid returned by the portal vein, and possibly by the hepatic vein, he became convinced of the communications of all the vessels in the "vascula ultima reticulata," and added another argument to the injections of Lieberkühn in favour of his opinion; for he says, "Injecti liquores colorati ex alio vasorum ordine facile in alium transeunt, qualis frequens Halleri veterumque, Walteri, denique et Rudolphi cel. extat experientia. Ipse equidem transitum aquæ limpidæ et coloratæ sæpius observari." Now with regard to the injections of Lieberkühn, I can only repeat with Kiernan, that *if* the lobular venous plexus or "vascula ultima reticulata" were filled, actually, from the artery, the only route which the injection could have taken must have been through the capillaries of the excretory ducts and vasa vasorum, and then through the portal vein. But with regard to the water experiment, I am quite satisfied of its utter inadequacy to elucidate so delicate a point as that under discussion. In my own experiments, made with a view of assuring myself of the nature of these plexuses, I have not been content with my injection unless I could distinctly trace with the aid of the microscope each capillary vessel from the interlobular vein to the intralobular vein, and this I have never failed to do in a successful injection from the portal vein; or in the opposite course when the hepatic veins have been filled. But in the most successful injection from the artery, when the capsular arteries have been beautifully filled, I have never observed more than a few red points in the circumference of the lobules. There is, however, in the consideration of this question, one circumstance which appears to have been altogether overlooked by Müller, but which seems to me to be fatal to the opinion which he entertains with regard to the distribution of the arterial blood. The ducts are abundantly supplied with blood from the arteries; indeed to so great an extent, that in a well-injected liver their coats appear to consist almost wholly of the ramifications of minute vessels. Now if the aggregate of the surface formed by the ducts, which is thus covered with vessels supplied from the artery, be considered, it must be evident that very little can be left for the "vascula ultima reticulata." And if conjointly with this fact, the difficulty of injecting the lobules from the artery be considered, it must be admitted that Müller carries his dogma somewhat too far, in asserting without limitation "that the arterial blood of the hepatic artery and the venous blood of the porta become mixed in the minute vessels of the liver."

The *hepatic veins* return the whole of the venous blood from the liver to the general venous circulation. They commence in the centre of each lobule by means of a small vein, the *intralobular*, which collects the blood after its circulation through the lobular venous plexus. The intralobular veins pour their current into the *sublobular* veins, and these latter unite to form the hepatic trunks, which terminate in the inferior vena cava. The hepatic differ from the portal veins in being more immediately in contact, and more closely connected with the substance of the lobules. Thus the intralobular veins are embedded in the substance of each lobule, and the sublobular inclosed in canals formed by the bases of the lobules, and therefore by that part which is uninvested by the lobular capsule. The hepatic trunks differ

* Having, through the kindness of Mr. Liston, had an opportunity of examining with the microscope some of the injections of Lieberkühn of different tissues, I can bear testimony to their beauty and wonderful minuteness, and can fully appreciate the deservedly high estimation in which they are held among the physiologists of Germany.

from the preceding in being lodged in canals formed by the capsular surface of the lobules, the *hepatic venous canals,* which are analogous to the portal canals excepting in the absence of a proper investment of Glisson's capsule. It follows from this circumstance, that there are no vessels in connection with the hepatic veins at all resembling the vaginal branches and plexuses of the portal vein. The general course of the hepatic veins is from the two surfaces and free margin of the liver towards the vena cava in the posterior border; that of the portal vein radiates from the transverse fissure in the centre of the under surface to all parts of the circumference; hence the two veins cross each other in their course, the former proceeding from before backwards, and the latter from the centre towards the circumference. In examining either of these sets of vessels, we should, therefore, be guided in the direction of our section by this peculiar arrangement. There is another mode by which we arrive at a knowledge of the means of discriminating between the two veins in a section. The hepatic vein being closely adherent to the lobules forming the canal in which it is lodged, remains open, and retains the form of its cylinder upon the face of a section; it may also be recognised by being solitary. The portal vein, on the contrary, being surrounded by the loose, vasculo-cellular web of Glisson's capsule, is permitted to collapse; it is also characterised by being associated with a branch of the hepatic artery and duct. In the consideration of the hepatic veins I shall describe, first, the intralobular, next the sublobular, and then the hepatic trunks.

In the centre of each lobule is situated an *intralobular vein* (*fig.* 34, 5,) which is formed by the convergence of from "four to six or eight" minute venules, from the processes upon the surface of the lobule. In the superficial lobules, the intralobular vein commences directly from the surface, and the minute venules by which it is formed may be seen in an ordinary injection converging from the circumference towards the centre. The vein then takes its course through the centre of the longitudinal axis of the lobule, and piercing the middle of its base opens into the sublobular vein. The intralobular veins have no direct communication with the portal vein or with the hepatic artery, and they simply serve to collect the blood which has circulated through the lobular venous plexus, and convey it into the general current of the hepatic veins.

The *sublobular veins* (*fig.* 34) are named from their position at the base of the lobules. They are lodged in canals which are formed by the bases of all the lobules of the liver. They are extremely thin and "delicate in texture," and lie in close contact with the substance of the lobules, so that upon laying open one of these veins, the bases of the lobules may be seen distinctly through its coats. In the centre of the base of each of the lobules will be observed the opening of the intralobular vein, so that the whole internal surface of the vein is pierced by these minute openings. In the smaller portal veins, on the other hand, where a number of small foramina were seen upon the internal surface of that side of the vessel which lay in contact with the canal, and where the outline of the lobules was also perceptible, it was observed that the small openings corresponded with the interlobular spaces, and were the entrances of the interlobular veins.

The *hepatic trunks* receiving the blood from the sublobular veins take their course along the "hepatic venous canals," and terminate by two large openings corresponding with the right and left lobes in the inferior cava, at the point where that vessel is lying deeply imbedded in the posterior border of the liver. A number of minor hepatic veins also terminate in the cava at this part of its course. The *hepatic venous canals* resemble the portal canals in being formed by the capsular surfaces of the lobules, lined by a prolongation of the proper capsule. The hepatic trunks are thick and dense in their structure, and their external coat is composed of "longitudinal bands." From the thickness of their texture the outline of the lobules is not apparent through their coats, nor have they any intralobular veins opening into them.

The coats of the hepatic veins are supplied with blood by the hepatic artery, and the venous blood is returned to the ramifications of the portal vein.

The *lymphatic* vessels of the liver are divisible into the deep and superficial. The former take their course through the portal canals, and through the right border of the lesser omentum, to the lymphatic glands situate in the course of the hepatic artery, and along the lesser curve of the stomach. They are easily injected (by rupture of course) from the hepatic ducts, and Kiernan remarks, that "injection sometimes passes from the arteries and portal veins into the lymphatics. I have frequently seen them in the right border of the lesser omentum, when distended with injection, as large as small veins. The *superficial lymphatics,* (*figs.* 32 and 33,) are situated in the cellular structure of the proper capsule, over the whole surface of the liver. Those of the convex surface are divided into two sets; 1st, those which pass from before backwards; and 2d, those which advance from behind forwards. The former unite to form trunks, which enter between the folds of the lateral ligaments at the right and left extremities of the organ, and of the coronary ligament in the middle. Some of them pierce the diaphragm, and join the posterior mediastinal glands; others converge to the lymphatic glands situated around the inferior cava. Those which pass from behind forwards consist of two groups; one ascends between the folds of the broad ligament, and perforates the diaphragm to terminate in the anterior mediastinal glands; the other curves around the anterior margin of the liver to its concave surface, and from thence to the glands in the right border of the lesser omentum. The lymphatic vessels of the concave surface are variously distributed according to their position; those from the right lobe terminate in the lumbar glands;—those from the gall-bladder, which are large and form a remarkable plexus, enter the glands in the right border of the lesser omentum; and those from the left lobe converge to the lymphatic glands situated along the lesser curve of the stomach.

The *nerves* which supply the liver are derived from the systems both of animal and organic life; the former are filaments of the right phrenic and two pneumo-gastric nerves, and the latter of the solar plexus. The branches from the right phrenic nerve descend by the side of the inferior cava, to unite with the hepatic plexus in the right border of the lesser omentum. Swan describes a small ganglion, to which filaments converge from the right semilunar ganglion and right phrenic nerve, as being the medium of communication between the phrenic nerve and the hepatic plexus. The branches of the pneumo-gastric nerves pass between the two layers of the lesser omentum to its right border, and pursuing the course of the hepatic artery are distributed with the hepatic plexus to the gall-bladder and along the portal canals. The *hepatic plexus* proceeds from the solar plexus and surrounds the hepatic artery to the transverse fissure; its filaments then accompany the branches of that vessel to their ultimate termination, and some few are observed to ramify upon the portal vein.

Progressive development of the liver in the animal series.—The liver in its simplest condition is a mere inflection of the mucous lining of the alimentary canal, forming a small cœcal recess or follicle. The capillary vessels ramifying upon the parietes of this follicle pour their secretion upon its internal surface, and it is thence conveyed to the alimentary canal to be mingled with the ingesta. In this its most rudimentary form the liver would appear to be present in the *Laginella*, a small cilio-brachiate polypus described and figured by Dr. Arthur Farre.* Upon the stomach of the *Laginella* are seen several minute cœca which open into its cavity; they are usually empty when the animal has been for some time without food, but become filled with a brownish fluid after a meal. The next most elementary form of the hepatic cœcum is seen in the single lengthened follicle discovered by Owen in the *ascaris halicoris*. This follicle opens into the alimentary canal at about one-third from its oral extremity. Among the *Annelida*, as in the medicinal leech (*fig*. 69, vol. i.) the liver is represented by numerous simple cœcal pouches appended to each side of the digestive canal. The next step in the complication of the organ is observed in the lengthened filiform tubuli which are connected with the sides of the canal in the Aphrodita. These are narrow and constricted at their commencement, dilating gradually as they proceed farther from the intestine, and terminating by a small oval sac. In other species of the same genus and in the Arenicola (*fig*. 70, vol. i.) they display a tendency to ramify, by developing small cœcal pouches from their sides. In these terminal sacculi Pallas discovered a " bitter fluid, of an olive-brown or greenish-black colour," which he conceived to be the juices of marine plants which had gained admission into the tubuli through their openings of communication with the intestine, but which, it is more than probable, was the proper biliary secretion of the tubes themselves. In the class *Insecta* the hepatic cœca vary in progressive development from the simple vesicular dilatations observed upon the digestive canal of the Lampyrus splendidula, or the simple cœcal tubulus of the carnivorous Cicindela, to the numerous cœcal follicles of the Dytiscus, or to the more lengthened tubuli of the Blatta orientalis. Throughout the whole of the class the character of the liver is tubular, the development and extent of the tubuli depending upon peculiarities in the food or habits of the animals. In *Arachnida*, the cœcal follicles are short, and terminate at their extremities in a cluster of numerous rounded vesicles, which give to the organ a lobulated appearance. They are seen in the Scorpion, in *fig*. 83, *c*, *c*, page 204, vol. i. In the class *Crustacea*, the hepatic organ assumes a higher and more complicated character; the simple cœcal follicle of Insecta becomes branched and ramified, of which we have a good example in the Argulus foliaceus, delineated by Müller. In the Astacus fluviatilis (*fig*. 214, page 483, vol. i.) the hepatic follicle is more branched than in the Argulus; and in the Pagurus striatus (*fig*. 215, page 484, vol. i.) the liver is composed of an extraordinary assemblage of ramified follicles. In the hepatic organ of the Squilla mantis we perceive a remarkable transition from the simple branched and ramified follicle of the lower Crustacea to the higher forms of the organ in the molluscous classes. Upon the exterior it is lobulated, and each lobe is composed of a congeries of minor lobules which appear like granulations upon its surface. Examined in its interior it presents a primary dilated sac of considerable size, from which branch off a number of secondary sacs of smaller dimensions, and these latter are studded over every part of their surface with minute cœcal follicles of a rounded form. In the subregnum *Mollusca* the liver is of large size, and approaches in external form to the solid and lobulated organ of vertebrata. In internal conformation we may still trace among the lower classes a close analogy with the ramified tubuli of Articulata. Thus in the class Gasteropoda the gland is composed of cœcal pouches, which divide and subdivide into smaller and smaller follicles and terminate in small dilated sacs. They may be compared in their disposition to the stem, branches, twigs, and fruit of a cluster of grapes. A liver of this kind is seen in the Helix pomatia. In the Murex triton the follicular structure of the organ would appear to be lost. The external surface presents a lobulated form, but the interior is composed of a delicate spongy tissue, consisting of larger and smaller cells, which may all be inflated from the excretory duct. This seeming difference in the structure

* Philosophical Transactions, 1837.

of the organ is, however, more apparent than real, for the numerous cells may be considered as so many follicles from which smaller follicles are developed. The cellular character of the organ depends upon the more extensive subdivision of the follicles, their assemblage in greater numbers, their consequent compression, and the adhesion of their parietes. In the Sepia family the spongy structure of the hepatic organ is still more distinct. It is channelled into numerous canals, from which smaller canals branch off in various directions; from these branches cells are developed, and the parietes of the cells are every where surrounded by smaller and smaller cells, the entire texture being very similar in arrangement to the cellular lung of the higher reptilia.

The liver in *Vertebrata* is more close and complex in its structure and less amenable to the observations of the anatomist than in the inferior series. We observe nothing, even in the lowest fishes, which bears any direct comparison with the cellular structure of the liver of Cephalopoda. The general character of the organ in fishes is loose and flabby, shewing that, although difficult to demonstrate, its internal texture evidently contains numerous tubuli. If the efferent duct of the liver of a fish be inflated, the whole organ appears distended; hence we might infer that the primitive structure of the organ is precisely the same, consisting in the ramifications of the hepatic tubuli or ducts, the increased wants and higher position of the animal demanding an augmented extension of surface. This is the great principle in the development of all glandular organs—extension of surface. The simple follicle is sufficient for an animal so low in the scale as a cavitary entozoon, but as the functions of the animal increase, its simple follicle must be extended to a greater length, or branched or ramified; and as high in the animal scale as the Vertebrata these subdivisions have attained so great a degree of minuteness that they are demonstrable to the practised eye only through the aid of the highest microscopic powers.

Müller arranges the glandular system into *simple* and *compound* glands. The former he divides into two groups: 1. "*simplest glands*," which "are mere recesses of greater or less dimension in the surface of a membrane;" and 2. "more complicated forms," in which several of the recesses are assembled together and open by so many distinct mouths, or they unite and form a common duct which terminates by a single opening. The "compound glands" he likewise subdivides into two groups: 1. those which "ramify with a certain degree of regularity, the principal trunk giving off branches laterally at certain intervals, these sending out in the same way side branches, which in their turn afford a third set." This disposition constitutes lobulated glands, and is the type of conformation of the liver in Invertebrata. 2. "The second group of the glands with ramified secreting tubes consists of those in which the ramification is irregular, and in which there is no division and subdivision of the gland into" secreting "lobules. The liver of Mammalia belongs to this group."

The form of the liver in *Fishes* corresponds with the direction of the long axis of the body; thus, for instance, it is elongated, and consists of a single lobe in the eel, while in the skate it is broad and extends into each lateral half of the abdominal cavity. In other fishes it is variously divided into lobes, and is often placed altogether on the left side of the body. In the class *Amphibia*, the liver also corresponds with the form of the body of the animal: in the frog it is short and divided into two primary lobes and several lobules; in the lengthened forms it is long and less divided. In the class *Reptilia* the liver is large, and bears an equal relation to the form of the visceral cavity. It is long and undivided in Ophidia, and short and divided into a right and a left lobe in Sauria and Chelonia, the two lobes being spread out over the intestines. In *Birds* there is great uniformity in the form and size of the liver. It is smaller in proportion to the bulk of the body than in Reptilia and Fishes, and larger than in Mammalia. It is situated in the middle line of the visceral cavity, and receives the heart into a depression upon its under surface. In the class *Mammalia* the liver is very much reduced in size, and is more compact and firm than in the lower vertebrata. In animals with simple stomachs it is situated in the middle line of the abdomen. In others, with large or compound stomachs, it is pressed towards the right side. The number of lobes does not depend upon a greater or less division of the liver into parts in accordance with the activity and mobility of the animal, but obeys a law in the animal economy, by which new parts are superadded in proportion to the increase of the wants of the creature. Man is placed at the foot of the scale in the progressive complication in external form of the liver of vertebrata; the entire organ may be considered in him as a central lobe, the lobus Spigelii being the rudiment of a second or right lobe. The liver of the ourang offers the same character. Ruminants have also a liver which presents the most rudimentary form of division. The liver of man is the type of the central or principal lobe, to which are added upon each side, in the animal scale, a right and a left lobe, and from these latter are developed a right lobule and a left lobule. This most complicated form of liver, consisting of five lobes, is met with among Carnivora and Rodentia; and throughout Mammalia, the successive additions and subtractions from this normal type form a constant and generic character. Besides this real division of the liver into five lobes, fissures of various depth are constantly met with, as in man, which give the appearance of a much greater subdivision. These secondary portions are to be looked upon as the mere results of separation, and have no relation with the primitive type. A most extraordinary form of liver is met with in a small rodent animal from Cuba, the Capromys, in which the whole surface is divided by deep fissures into small masses of a triangular and quadrangular form, like the kidney of a bear.

A similar arrangement is seen upon the visceral surface of the liver in the Llama.

The *gall-bladder* is absent in all invertebrata, the efferent ducts of the biliary organ terminating for the most part by several openings in the digestive stomach. In *Fishes* the gall-bladder is observed for the first time in the animal series, but it is not by any means constant in its existence. It is absent in many genera, and in these cases is frequently replaced by a dilatation upon the hepatic duct and by several efferent tubes. In the class *Reptilia* it is invariably present, and varies considerably in form, in the different genera. In serpents it is placed at the extremity or even beyond the liver, and occupies the space formed by the pyloric contraction of the stomach. The cystic duct is consequently extremely long. Among the Chelonia the gall-bladder is enclosed within the substance of the liver, and receives its secretion through the medium of cyst-hepatic ducts. Some of these ducts unite also with the cystic duct and constitute a ductus communis choledochus. In *Birds* the gall-bladder is occasionally absent, as in Pigeons, Toucans, &c. without supplying to the comparative anatomist a sufficient reason for the peculiarity; being present and absent in the same natural genera and under precisely the same circumstances of food and climate. The bile is brought from the liver by two ducts, a cyst-hepatic duct which opens into the gall-bladder, and an hepatic duct which terminates in the duodenum near to the cystic duct. When the gall-bladder is absent, both hepatic ducts terminate in the duodenum. There is no instance in the whole class of a ductus communis choledochus. In *Mammalia*, the gall-bladder is by no means constant; it is deficient as a general rule, to which there are several exceptions, in herbivorous animals, as in the horse, stag, elephant, peccary, tapir, whilst it is present in the ox, sheep, goat, antelope, &c. In the first giraffe examined in this country by Owen it was absent; in the next he found two. Upon the hepatic duct in the elephant, near to the duodenum, there is a remarkable dilatation. In the cat and seal the ductus communis choledochus is dilated in the same situation. It is not uncommon to find a double gall-bladder or two gall-bladders in the cat; in the kinkaju this is supposed to be the normal condition; and in the Museum of the Royal College of Surgeons there is a preparation, preserved by Hunter, of the liver of a small animal in which are three gall-bladders.

Throughout Invertebrata the bile is secreted from arterial blood. In Fishes the portal vein is formed by veins returning from the tail and occasionally from the air-bladder and genital organs. In Reptiles a part of the blood from the lower extremities unites with that from the alimentary canal to constitute the portal circulation. In Birds the portal vein also receives a part of its blood from the tail and lower extremities by means of its communication with the pelvic veins. (*Fig.* 171, *u*, *v*, *z*, page 338, vol. i.) Injections of the portal vein carefully conducted, as well as injections from the internal iliac vein, have shewn that a venous communication subsists between the smaller branches of the two systems in the large intestines, even in man. In support of this communication Müller, in his Physiology, quotes the observations of Retzius: "Professor Retzius, of Stockholm, however, has informed me that he has discovered in man some minute communications between the veins of the intestines and the branches of the vena cava. When he injected the vena cava and vena portæ with fine injection of different colours, he found that the whole meso-colon and colon sinistrum were injected with both colours, and veins belonging to the two systems at several places formed anastomoses. The veins of the colon and meso-colon, which belonged to the system of the vena cava and entered the left renal vein, lay superficially, while those which belonged to the vena portæ lay for the most part nearer the mucous membrane. The external surface of the duodenum also had received injection from the vena cava. M. Breschet too has filled the inferior mesenteric vein from branches of the inferior cava, and Schlemm has discovered distinct communications of the inferior mesenteric vein with branches of the inferior cava about the anus." Besides these communications between the two systems occurring in the pelvis, Kiernan points to another most important communication upon the surface of the liver. "The capsular veins," he says, "are branches of the portal vein; these vessels communicate freely with branches of the phrenic veins. In some cases of atrophy of the liver, and in cases in which the circulation through the liver has been for some time obstructed, a collateral circulation is established by means of the communications which take place between the capsular branches of the hepatic artery and portal vein and those of the phrenic artery and vein." In diving animals, as in the otter and seal, in which large venous reservoirs exist upon the inferior cava, for collecting the returning blood during submersion, the hepatic veins are muscular. Kiernan observes with regard to the hepatic veins of the seal that they "differ in many respects from those of any other animal I have examined. The intralobular veins at their exit from the lobules do not as in other animals terminate immediately in the hepatic veins: these vessels enter the hepatic venous canals, where they unite into branches, which, like the vaginal branches of the portal vein, are connected by a fine cellular tissue, with which they form around the hepatic veins a cellulo-vascular sheath precisely similar to that surrounding the branches of the portal vein. The structure of the two sheaths is similar, but their uses are different. That of Glisson's capsule has been explained; the capsule of the hepatic veins in the seal appears destined to admit of the muscular contractions of these vessels." "The external coat of the hepatic veins is composed of circular fibres which in the larger vessels form a complete tunic. In the smaller vessels the fibres are arranged in the form of circular fasciculi, which are connected with each other by oblique intermediate fibres. All the fasciculi do not extend completely round the veins; some, dividing into two portions, unite with fibres from those above and below, and form other fasciculi." "In the porpoise the hepatic veins are connected to their canals; no circular fibres are seen in their coats. Their external surface is reticulated, the ridges corresponding to the interlobular fissures, where the interlobular cellular tissue is continuous with the cellular coat of the veins. The mouth of an intra-lobular vein occupies the centre of each space circumscribed by the ridges."

The distribution of the vessels in the liver in the three great classes, Reptilia, Aves, and Mammalia, has been ascertained to be the same with that which has been so completely illustrated in the discoveries of Kiernan. In Fishes but few observations have been made, but analogy would lead us to infer that the general arrangement must be the same.

Development of the liver in the embryo.— The development of the liver in the embryo commences so early in Mammiferous animals, hurries so rapidly through its different phases, and is completed so soon, that it has hitherto been impossible to obtain any connected and precise information with regard to its progress. The observations of eminent physiologists made from time to time have, however, shewn that the mode of its development is in all respects similar to the development of the liver in the chick. Indeed, the egg of the bird is in the highest degree favourable to anatomical examination, both on account of its large size and the facility with which the incubated egg may be obtained from hour to hour, and from day to day. The principle of development therefore being the same in the ovum of the bird as in Mammifera, I shall here trace the progress of the liver in the chick according to the most recent researches of Baer.

In the embryo of the fowl at the commencement of the third day, the common vein of the body is embraced by two pyramidal cœcal pouches which communicate by their bases with the intestinal canal, and which shoot forwards so as to carry before them a fold of the vascular layer of the germinal membrane, in which they begin to ramify by giving off cœcal branches from their sides and extremities. These two cœcal tubuli with their corresponding ramifications form two flattened processes, which represent the two lateral lobes of the liver. By the end of the third day the two processes resemble folds of the vascular layer in which the tubuli are seen ramifying; they have increased in size and almost surround the vein. On the fourth day the liver has the appearance of two flattened processes which enclose the vena portæ. The hepatic tubuli have become lengthened and further removed from the intestine, and have ramified more freely in the vascular layer. By their bases the hepatic tubuli approach nearer to each other, and at the end of the fourth day they coalesce and form a common tube. On the fifth day the liver has attained considerable size; its two lobes have become thick and appear to possess a spongy texture in their interior. The hepatic ducts are connected with the intestine by a common duct, the ductus communis choledochus; and the portal vein gives off large branches which are distributed among the ramifications of the ducts. On the sixth and seventh days the liver receives an abundance of blood and is nearly as red as the auricle of the heart. The left lobe is sensibly smaller than the right. On the eighth, ninth, and tenth days the liver has lost its great redness and presents a yellowish brown tint; the vessels have diminished in calibre, while the parenchyma has increased, and the gall-bladder has become apparent. The succeeding days augment the size of the organ, and mould it to the form which it possesses after the escape of the chick from the egg; it begins to secrete bile; and the gall-bladder assumes the pyriform shape which it retains in after-life.

In the human ovum the formation of the embryo commences visibly at about the third week of intra-uterine existence; the parietes which separate the embryo from the ovum begin to be developed, and rudiments of the intestinal canal, the liver, and the heart soon become distinctly visible. Upon its earliest appearance the liver is of large size, and between the third and the fifth week is one-half the weight of the entire body, divided into several lobes of a reddish grey colour, and receives a large proportion of blood from the omphalo-mesenteric vein. From the fifth to the eighth week the liver extends as low as the margin of the pelvis; it is soft, almost pulpy, and greyish in colour. The gall-bladder is developed in the form of a lengthened filiform cord, having an extremely minute canal through its centre. By the third lunar month the liver extends nearly to the pelvis and almost fills the abdomen, and the right lobe has increased somewhat beyond the left. The texture is more firm and of a redder colour, and the gall-bladder is long and conical. At the fourth lunar month the liver is still prolonged nearly to the margin of the pelvis, but the left lobe is evidently shorter than the right. The gall-bladder is elongated, straight, and vertical in direction, and contains a little mucus. Upon its internal surface a few rugæ begin to be perceived; it receives no bile, although a small quantity of that fluid is secreted by the liver and poured into the intestine. By the fifth lunar month the liver has acquired an increased consistence and deeper colour. It no longer descends so low as the pelvis, but appears to have diminished in bulk in proportion with the size of the abdomen. The gall-bladder assumes a more horizontal direction, and the contained mucus has a yellowish green tint. The openings of the ductus choledochus and pancreatic duct, at first placed at a considerable distance from each other, approximate and produce less projection of the mucous membrane. By the sixth lunar month the descent of the liver is still more curtailed, the fœtus increases in development from before backwards, and the organ becomes more horizontal. By the seventh lunar month the gall-bladder contains bile, and the mucous membrane becomes rugous and reticulated. At the eighth month, and during the ninth and tenth months, the liver becomes still more horizontal in position and of a deep red colour. The bile is more abundant and of a clear green tint. At the tenth month, that is, at birth, the relative proportion of the liver to the rest of the body is as 1 to 18 or 20; the average in the adult being as 1 to 36. After birth the size and weight of the liver diminish until the end of the first year, for, according to Meckel, the liver of the newly born infant weighs one-fourth heavier than at the age of eight or ten months. The borders of the liver are rounded in the fœtus, and the inferior surface is convex. The lobes are nearly equal until birth, after which the left diminishes in size, the right remaining stationary or growing but little, and at the age of one year the left lobe is scarcely one-half so large as at birth. The texture of the liver in the fœtus is soft and fragile and apparently homogeneous in structure; during the earlier periods its colour is a light brownish grey; at about the mid-period it becomes deeply red, and after birth loses a portion of its colour from a diminution of the quantity of blood circulating through it.

Uses of the liver.—The liver performs two most important functions in the animal economy:—1, it separates from the venous blood of the chylopoietic viscera certain elements which are needful to digestion; and, 2, it depurates the venous blood. The first of these functions constitutes the secretion of bile. The second is evinced in a comparative examination of two of the great depurating organs, the lungs and the liver, in the various classes of animals, where the latter will be constantly found in exact relation with the development of the respiratory organ, and with the necessity for the removal of a larger quantity of hydrogen and carbon from the blood. Thus, in herbivorous animals, the liver is small; it is small also in monkeys and in man. It is large, and has reached its highest development amongst Mammiferous animals in Carnivora. In birds it is larger in proportion than in Carnivora, from the greater necessity of a highly oxygenated blood in that class of animals. In Reptiles, with cold blood and a low degree of respiration, it is large; it is large also and for the same reason in Fishes; and very large among the Invertebrata.

Secretion of bile.—The bile, which would appear, from the existence of follicular recesses in the alimentary canal, to be produced in all animals from the lowest to the highest, is secreted in man and in vertebrata from the blood during its circulation through the lobular venous plexus in the lobules of the liver. Hence it becomes a question of importance to physiology to decide from what kind of blood it is eliminated. If, according to Kiernan, all the arterial blood of the hepatic artery become venous previously to its passage into the lobular venous plexus, *the bile must be secreted from venous blood;* that venous blood being derived from the capillaries of the chylopoietic organs, and from the capillaries of the hepatic artery. I have given Kiernan's reasons for the belief that this is the truth; and in corroborating the results of his injections I must also add my own testimony to his view of the secretion of the biliary fluid. Müller, entertaining, as I have already shewn, a different opinion with regard to the distribution of the vessels of the liver, believes that the bile is secreted from a *mixed arterial and venous blood,* resulting from the termination of both the hepatic artery and portal vein in the "vascula ultima reticulata," or lobular venous plexus. From the undecided manner in which he expresses this opinion, I am tempted to give the quotation in which it is contained, that my readers may judge how far he be really in earnest in his assertion. "It is known that injection thrown either into the hepatic artery or into the portal vien, fills the same capillary net-work, from which, on the other hand, the hepatic veins likewise arise."

Since reading the above paragraph I have injected twelve livers for the purpose of deciding the question, in my own mind, of the ultimate termination of the hepatic artery; but I have in no instance succeeded in forcing injection into the lobular venous plexus, although every other part of the organ has been beautifully injected. I have therefore been forced to the conclusion that some mistake must exist with regard to this passage, and that, although perfectly true when confined to the portal vein, Müller cannot mean that the capillary network (lobular venous plexus) from which the hepatic veins arise, is actually filled from the *hepatic artery.* But he continues, "It appears, therefore, that the arterial blood of the hepatic artery, and the venous blood of the porta, become mixed in the minute vessels of the liver, and that the secretion of bile *probably* takes place from both." Now, with deference to Müller's judgment, the question, with our present knowledge upon the exact anatomy of the liver, ought not to be one of probability or surmise;—does it? or does it not? But he appears far from satisfied, in relying for the support of his argument upon his own peculiar theory of the arrangement of the hepatic vessels, and, as if distrusting its efficiency, he exclaims in another page of his Physiology, "But the possibility of bile being secreted from arterial blood is demonstrated by the cases in which the vena portæ enters the vena cava directly instead of being distributed through the liver. Mr. Abernethy observed this anomalous structure in a male child ten months old; and Mr. Lawrence has detailed a case in which the same malformation existed in a child several years of age. In Mr. Abernethy's case however the umbilical vein was still pervious and branched out in the substance of the liver; it is possible therefore, as Mr. Kiernan remarks, that the arterial blood, after having nourished the liver, was poured into the branches of the umbilical vein, just as it is in the normal condition, according to his opinion, poured into branches of the portal vein, and the secretion of bile therefore might still have been derived from venous blood."

"M. Simon and Mr. B. Phillipps have inferred from experiments which they performed, that the bile is secreted from the blood of the portal vein. But Mr. Phillips found that after the vena portæ had been tied the secretion of the bile still continued, though in diminished quantity; and he concludes, therefore, that it is formed both from arterial and venous blood. He perceived no change in the biliary secretion when the hepatic artery was tied."

The cases recorded by Wilson, Abernethy, and Lawrence are interesting, but they do not appear to me to affect in the slightest degree the arguments on either side of the present question. It is true that it might be asserted in behalf of Müller's opinion, that the blood sent to and circulating in the liver was arterial, and that from this alone bile was secreted, for in both cases bile was found in the gall-bladder, while the vena porta emptied itself into the vena cava. On the other hand it was ascertained by Kiernan in the only one of the three cases in which the liver was preserved, that the umbilical vein (hepatic portal) was pervious, of considerable size, and ramified as usual through the portal canals and terminated as usual in the lobular venous plexus. Now, although the hepatic portal vein (umbilical) did not obtain its accustomed supply of blood after the placental circulation was arrested, from the abdominal portal vein, yet there is no reason for supposing that it did not collect the venous blood from the capillaries of the arteries supplying the coats of the excretory ducts and other vessels. Again, the transmission of the remaining portion of the arterial circulation through the vaginal, the interlobular, and lobular arteries must have seriously affected its arterial character if it have not indeed altogether converted it into venous blood. Although Mayo, who took part in the examination of this liver, observed upon this point that "it cannot be supposed that the arterial blood, in its passage through the vasa vasorum into the branches of the umbilical (hepatic portal) vein underwent the usual change into venous blood; and it was still, he contended, arterial blood, though less pure in character, which was conveyed through venous canals into the secreting part of the liver."

Now it may be fairly presumed that blood which is not arterial must be venous; but it must at the same time be admitted that the normal degrees of arterialisation are various in individuals, and different in different regions of the body at the same moment; so that no satisfactory argument can be sustained upon an assumption of the sub-arterial character of the blood. I would rather suggest another train of reasoning. The abdominal portal vein returning blood possessed of peculiar properties from the chylopoietic viscera terminates in a rare anomaly in the inferior cava, so that the portal blood is mingled with the general venous current of the system. The lungs receiving this blood exert their appropriate influence in separating from it a portion of the noxious elements with which it is combined; but it cannot be supposed that this blood will return to the heart as pure in character as that which has circulated in the usual way through the other depurating organ, the liver. No; it still contains the elements from which bile may be secreted, and a larger portion than usual is therefore sent to the liver, that this secretion may be eliminated. Hence we cannot treat the blood thus flowing into the liver from the aorta in a much larger current than natural ("in ordinary cases one principal artery is found in each canal; in this case two, and in some places three arteries of equal calibre were found in each canal") as mere arterial blood destined for nutrition alone; but we must regard it as a fluid bearing in its course the elements of the bile; and therefore, whether it be poured through the capillary channels of the lobular venous plexus, or through those of its own developing in the substance of the lobules, it is nevertheless an abnormal influence which cannot be tested by man's decision, but is part of the compensating principle so admirably displayed by nature in all her operations.

With regard to the evidence of experimental operations upon living animals, this must at all times be unsatisfactory and inconclusive from the difficulty of observing and appreciating the consequences of the experiment, and from the morbid condition impressed upon the animal by the serious nature of the operations themselves. Those which have been performed are favourable to the conclusion that the bile is separated from the blood of the portal vein. But I have little faith in such experiments;—after the ligature of the portal vein, the animal lives but a short period; the blood arrested in its current is conveyed through the medium of inosculations into the general venous circulation, and then, as I have above suggested, if the animal survive sufficiently long, the bile may be secreted from the fluid which contains it, viz. from the arterial blood.

Cuvier entertains the opinion, that the bile is secreted from venous blood, as may be perceived in the following passages:—"Le foie des animaux vertébrés a en effet un caractère qu'il ne partage avec aucune autre glande; c'est que sa sécrétion est alimentée par du sang veineux; par du sang qui a déjà circulé, et qui n'est pas retourné au cœur, ni par conséquent au poumon. Cette circonstance a lieu, non-seulement dans des animaux à circulation double, où tout le sang doit repasser par le poumon, avant de se rendre aux parties, le foie excepté; mais encore dans les animaux à circulation simple (les reptiles), où une si grande portion du sang artériel n'a point retourné au poumon, et tient par conséquent de la nature veineuse; c'est presque alors du sang deux fois veineux qui se rend dans le foie." May we not, therefore, from the powerful arguments afforded by anatomical investigation, and from our knowledge of the compensating energies aroused by nature in cases of anomaly,—may we not, at least until weightier reasons to the contrary shall be developed by the progressive discoveries of our improving science, conclude that *the bile is secreted from venous blood?*

The *quantity of the bile* is a question difficult to decide accurately; it would appear to be secreted most abundantly during digestion, when the augmented activity of the stomach would seem to be communicated to its neighbouring organ, the liver. Certainly it is evacuated from the gall-bladder into the digestive canal at that period. In animals which have been kept long fasting the gall-bladder is always greatly distended. Schultz observed, in an ox which had been kept for some time without food, from twelve to sixteen ounces of bile in the gall-bladder, and in another, after digestion, from two to four ounces only. In a dog which had not eaten for some time he found five drachms, in another, after digestion, about two drachms. In a case of abscess of the liver communicating with the gall-bladder and lung, recorded by Dr. Monro, the whole of the bile flowed through the fistulous canal and was discharged by coughing, "in proof of which," he says, "the fæces were of the same whitish colour and had as little smell as those of a person deeply jaundiced. The quantity of bile discharged by coughing was different at different times. It was *always greater after meals*, and especially for an hour or two after dinner. The quantity expectorated could not be measured with great accuracy from being mixed with mucus and saliva. The whole quantity in twenty-four hours was from ten to fifteen ounces; and, in this case, I had an opportunity of observing the effects of certain articles of food, and in particular of acids, of wine, and of different fruits, in increasing the quantity of bile."

Expulsion of the bile.—This process I have just shewn takes place more abundantly during digestion than at any other period. In all carnivorous and in most herbivorous animals there exists a peculiar provision for the collection of the bile during the period of abstinence, in a membranous reservoir, the gall-bladder. Some herbivorous animals, deprived of a distinct gall-bladder, have a compensating dilatation upon the hepatic duct. The use of this organ is to retain the bile until digestion demands its excretion. Those animals, therefore, that are provided with it are such as perform the function of digestion at variable intervals. But in those whose digestion is continuous, as is the case in many herbivora, the bile flows as it is secreted into the alimentary canal; being very probably provided more abundantly under the stimulus of a full stomach than during the abstinence from food or during sleep. In the contracted state of the duodenum the small and oblique opening of the ductus communis choledochus is closed to the passage of the fluid; it therefore regurgitates along the cystic duct into the gall-bladder. In the slight ascent along this tube it is facilitated by the spiral valve, which also serves to restrain its too sudden emission during spasmodic action of the abdominal muscles. As soon as the duodenum becomes filled with the chyme from the stomach, the opening of the ductus communis choledochus is less compressed. The distension of the stomach, but more particularly the passage of the chyme along the pylorus into the upper part of the duodenum, causes a gentle pressure upon the coats of the gall-bladder which favours its emission; its contents are gradually expressed, and flowing along the ductus communis choledochus are mingled with the pulpy mass in the duodenum. This explanation of the process seems to have been entertained by Haller, and to have arisen in his mind from the consideration of the anatomy of the serpent, where the gall-bladder is far removed from the liver and is situated in the space formed by the contraction of the pylorus and its termination in the small intestine. Neither do I consider its truth invalidated by those cases in which the gall-bladder is partly imbedded in the liver, for in such instances that portion of the liver is compressed which immediately covers the fundus of the gall-bladder, or a part of the gall-bladder is exposed against which the duodenum may exert an equal compression. Müller conceives that the efferent ducts of glands are surrounded by "an extremely thin layer of muscular substance," which, although not demonstrable anatomically, he thinks to be placed beyond dispute by physiological observations. "The contractile power of the ductus choledochus in birds was known to Rudolphi. By irritating mechanically or by galvanism the ductus choledochus of a bird just dead, I have frequently produced a very strong contraction of it, which continued some minutes, after which the duct resumed its previous state. I have often excited strong local contractions of the ureters likewise, both in birds and rabbits, by the application of a powerful galvanic stimulus. Tiedemann also has seen motions of the vas deferens of a horse ensue on the application of a stimulus. It appears indeed that periodic vermicular motions are performed by the efferent ducts, at least by the ductus choledochus, in birds; for I have once observed in a bird just killed, contractions of the duct occurring regularly in pauses of several minutes, the tube dilating again in the intervals; and what was remarkable, the contractions took place in an ascending direction, namely, from the intestine towards the liver: and this seems to throw some light on the mode in which the bile at certain times, instead of being expelled into the intestines, is retained and driven into the diverticulum of the duct, namely, the gall-bladder; the complete closure of the mouth of the duct contributes perhaps to this effect. The discharge of the bile from the gall-bladder during digestion results probably from the mere pressure of the surrounding parts, and the action of the abdominal muscles, while the mouth of the duct is open: for I doubt if the gall-bladder is contractile; I could produce no contraction of it in mammalia and birds even with the most powerful stimulus of a galvanic battery." Dr. Monro considers the middle coat of the gall-bladder in man to contain muscular fibres; the muscular coat in the gall-ducts of the dog and horse are, he observes, quite distinct, and upon irritation he has seen the gall-bladder contract in a living animal so as to resemble an hour-glass. Andral thinks that he has perceived muscular fibres in the hypertrophied coats of the gall-bladder, and Ferrus records a case as occurring to Amussat where, in obstruction to the ductus choledochus by a gall-stone, the middle coat of the gall-bladder and ducts above the impediment was evidently muscular. This preparation was seen by Kiernan at the time that it occurred. The bile during its stay in the gall-bladder becomes inspissated by the removal of the fluid part of the secretion, which is most probably taken up by the numerous lymphatics which cover its surface.

The *uses of the bile* are threefold; 1. it acts chemically upon the chyme and produces the separation of the chyle; 2. it combines with the residuum and forms the fæcal matter; 3. it stimulates the mucous surface of the canal and promotes its secretion, and the contractile action of the muscular coat.

Red and yellow substances of Ferrein.—Since the period when anatomists were divided in their considerations of the liver by the two great contending opinions of Malpighi and Ruysch, the former maintaining its composition of glands, and the latter of minute vessels, the majority of observers have adopted the views proposed by Ferrein, who was the first to vindicate the existence of two distinct substances, which he named cortical and medullary. It was reserved for Kiernan in our own day to prove that "the structure of all the lobules is similar;" that "each lobule is the same throughout;" that "one part of a lobule is not more vascular than another;" and that "there is, therefore, no distinction of red and yellow substances in the liver; the red colour results from congestion only." This doctrine being now established as an undisputed truth, it is not surprising to observe that anatomists and pathologists differed in opinion with regard to the relative position and appearance which these two imaginary substances occupied in the respective livers which they chanced to examine, and upon which they established their decision. Thus we find that Ferrein described the medullary substance as being red in colour, and of a pulpy consistence, and the cortical as friable in its structure, and of a yellowish red colour. Autenrieth, on the contrary, found the red substance to be cortical and the yellow medullary. Mappes having obtained a liver in a different state of congestion, conceives that the yellow substance might be named *granulated;* he describes it as forming convolutions, one while like intestines, and another while branched, flat, or rounded; and the spaces between the convolutions as being rounded, or resembling oblong fissures filled with a brownish and loose substance. Meckel coincides with Mappes in the relative position of these parts; they are not, he says, placed as in the brain, one on the exterior, the other in the interior, but they alternate throughout the entire organ, the yellow substance forming the mass of the liver, and the brown filling the interspaces. Rudolphi objects to the terms medullary and cortical. Bouillaud asserts that the yellow substance presents itself in the form of granulations having the figure, colour, and arrangement of the secreting granules of the bile known, as he remarks, under the name of acini. These granules, he says, are surrounded by the brown substance, which therefore assumes an angular appearance; it is composed of a vascular net-work, and may be compared to erectile tissue. Andral, in his Anatomie Pathologique, says, "Lorsqu'on examine avec quelque soin un certain nombre de foies, l'on y reconnâit l'existence de deux substances: l'une rougeâtre, où se ramifie surtout le systeme capillaire de l'organe; l'autre blanche ou jaunâtre, qui semble surtout destinée à l'accomplissement de la sécrétion biliare. Dans l'état normal ces deux substances sont distinctes." The opinion of Ferrein is opposed by Portal and Cruveilhier: the former anatomist, after reproving certain modern authors who wished to combine the views of Malpighi and Ruysch by admitting that the liver was formed both of glands and of a prodigious number of vessels, contents himself by asserting that Ferrein's idea of the composition of the glands of the liver of two substances was gratuitous. To Cruveilhier the distinction of two substances appears ill founded, for he observes that the two colours when they exist, which is not constantly the case, do not belong to two distinct granulations, but to one and the same, which is yellowish in the centre where the bile predominates, and of a brownish red in the circumference where the blood is situated. Kiernan ranks Müller among the authors who entertain an opposite opinion to that of Ferrein, but I find upon referring to his work upon the glands, that he distinctly admits a kind of double substance although he objects to its designation, medullary and cortical; hence he observes:—"Diversam substantiam hepatis, utpote medullarem et corticalem, quæ per hepar totum undique obveniunt, qualem Autenrieth, Bichat, Cloquet, Mappes, atque etiam J. Fr. Meckel admittunt, equidem neque in historia evolutionis amphibiorum et avium, neque in hepate adultorum microscopice observato conspexi. Historia evolutionis hanc quæstionem evidentissime illustrat. Systema nimirum ductuum biliferorum in embryone amphibiorum et avium liberis finibus in superficie hepatis prominulis conspicuum. Sarmentula illa foliatim et paniculatim divaricata, colore e gilvo candido nitent, magnopere ab interstitiis sanguinolentis distincta. Hinc sane duplicis substantiæ species exoritur, quoniam circum ductuum biliferorum a tela conjunctiva expleantur, quæ ex subtilissimis fere constat vasculorum sanguiferorum retibus, in quibus arteriæ et venulæ advehentes in revehentes venas transeunt. Atque hæc sola est utriusque substantiæ notio. Sed in omnibus organis glandulosis fere idem obvenit." In his Physiology he is disposed to modify his previous idea of two substances, for he says, "From my researches, however, it results that there is but one kind of *real* hepatic substance, formed of agglomerated biliary canals; but the ramified divisions of this sub-tance being connected by a *vascular cellular tissue*, which is often of a dark colour, a contrast between this and the yellow substance of the acini is produced. A similar relation of the constituent parts of the liver exists in the embryo of the bird; in it the yellowish twig-like ramifications of the biliary canals are seen on the surface of the organ rising out of a reddish vascular tissue."

M. Dujardin, in an article entitled, "Recherches Anatomiques et Microscopiques sur le Foie des Mammiferes,"* has advanced some opinions which he conceives will throw a doubt over the labours of Kiernan. My space will not permit an analysis of his paper, but it will be obvious to all who may be disposed to read it, that he has not advanced a single new fact, but on the contrary has confessed the most imperfect and inadequate means of examination. Thus, he observes, "with an injection sufficiently fine we can inject the portal vein as far as the capillaries which surround the lobules." Therefore, according to him, the interlobular veins are capillaries, and we need not wonder that with such injection he gets no further, but denies the existence of vessels in the lobules altogether. The lobules, he says, are composed of glutinous corpuscules or globules, which leave channels between them, through which the corpuscules of the blood pass without alteration; at the same time by an action analogous to the phenomena of absorption and assimilation in the lower animals, these lobules separate from the serum the excrementitious particles which are excreted upon the surface of the lobule. The blood of the portal vein is transmitted through the lobule by a kind of "*filtration organique*," and from it the resinous matters of the bile are eliminated; the arteries, on the contrary, secrete the alkaline substances, which in the first instance dissolve the resinous substance, and afterwards constitute the true agents of digestion. M. Dujardin concludes his theoretical but ingenious speculations with an excuse for being obliged to give them to the world in their present imperfect state, and promises to renew his researches with perseverance. I feel pleasure in recording his promise, and have no doubt that by better directed injections in the human liver, using size and vermilion in place of oils and varnish, he will be induced to modify his views with regard to this most interesting organ.

Pathological anatomy of the liver.—If we consult the works of pathological writers upon this subject, we shall observe at every step of our progress the greatest ambiguity and difference of opinion to exist. The reasons for this want of consent upon the true nature of the diseases of so important an organ are not to be ascribed either to want of talented observers or of excellent observations, but solely to the ignorance which has hitherto prevailed with regard to the exact anatomy of the organ. I have shewn that the most celebrated authors found it necessary in starting with their inquiries to establish for their guidance a theory of the structure of the liver; this theory was based upon imagination or upon deceptive appearances; and upon this frail basis the crumbling superstructure of their pathological deductions is supported. The hypertrophy or atrophy of the white or of the red substance, and the wild speculations of pathological theorists, have now fallen into the shade before the light which recent discoveries have thrown upon the anatomy of the liver. Intimately associated with that anatomy, and with the knowledge of the distribution of the vessels, is the explanation of the mode in which the circulation is performed, and the elucidation of the causes which may give rise to impediment in its course; in other words, the principles of congestion. Indeed, so closely allied is that condition with the natural circulation, that Kiernan, in his paper upon the Anatomy and Physiology of the Liver, has deemed it a part of the subject to explain the various congestions to which the organ is liable, and the manner in which they may be imitated artificially. Upon this point we have, therefore, precise information, and the history of congestion we may regard with a feeling of satisfaction. The same observations, with the exact anatomy of the liver as a basis, have not as yet been extended to its diseases; our knowledge of these is therefore necessarily imperfect. Kiernan concludes his paper with a paragraph of much importance to this branch of pathology:—"While engaged in the examination of the natural structure of the liver, I have not been inattentive to the changes produced in it by disease; and, with the permission of the Society, I propose submitting to its consideration a paper on the morbid anatomy of this organ." Now this was written in 1838, and I trust that the time is not far distant when the additional labours of that excellent observer will be placed in the hands of the profession.

In the arrangement of the diseases of the liver I have adopted a physiological order, and shall consider its morbid conditions under the seven following heads:—

1. Diseases of the serous membrane.
2. Diseases of the mucous membrane.
3. Disorders of the venous circulation.
4. Disorders of biliary excretion.
5. Diseases of the parenchyma.
6. Disorders of function.
7. Entozoa.

1. *Diseases of the serous membrane.*—The serous covering of the liver, like serous membranes in other parts of the body, is liable to *acute inflammation*. The effects of this inflammation are also similar; the capillary vessels become over-distended and lose their power of contraction; coagulable lymph is effused upon the surface of the organ, and causes its mechanical cohesion to the contiguous serous membrane; the coagulable lymph becomes organised by the development of new capillary vessels from the meshes of the old, and the adhesions are traversed by vessels of larger size, and constitute a permanent bond of

* Annales Françaises et Etrangères d'Anatomie et Physiologie, 1838.

union between the peritoneum proprium and the peritoneum reflexum. In this state, adhesions are not uncommonly met with upon the convex surface of the liver, but not so frequently upon its concave side. The inflammatory action is confined to the peritoneum of the organ itself, and that of the parietes of the abdomen immediately in contact with it, and seldom extends to the serous membrane of neighbouring viscera. This is the *membranous hepatitis* of pathological writers, and is accompanied by considerable local uneasiness, and by sympathetic pains in various parts of the body, dependent upon the communication of its proper nerves with the nerves of other regions, as with the phrenic nerve, giving rise to pain in the right shoulder and chest, with cough; with the pneumogastric nerve, producing uneasiness at the cardia, pain along the œsophagus, dysphagia and nausea; and with the solar plexus and lesser splanchnic nerve, causing pain in the right kidney, &c. This disease is usually associated with chronic congestion of the substance of the liver, but exists, sometimes, quite independently of any internal morbid action.

As a consequence of *chronic inflammation*, the serous membrane is sometimes thickened and opaque and dense in its consistence; at other times it is less resisting than natural and easily broken.

Depositions are occasionally found in the subserous tissue of the liver as a result of chronic inflammation of the serous membrane. They consist most frequently of an atheromatous substance, and occasionally of thin plates, having a cartilaginous density and appearance. The gall-bladder is not unfrequently thickened in its coats by the deposition of fat, of tuberculous, or of calcareous substance. The latter has been described as ossified gall-bladder.

2. *Diseases of the mucous membrane.*—Inflammation of the mucous membrane of the liver is acute or chronic, and is more frequent than that occurring in the serous membrane. Being continuous with the mucous membrane of the duodenum, the lining of the biliary ducts and gall-bladder is constantly subject to sources of irritation from disorders of digestion, improper aliment, and stimulating substances taken into the alimentary canal, or from any cause giving rise to undue action in the intestinal mucous surface. Almost all the chronic diseases of the liver are to be referred to this prolific source, and it is also by means of this direct continuity that many of the therapeutic remedies exert their alterative influence. The effects of inflammation on the mucous membrane, are

a. Thickening.
b. Softening.
c. Hæmorrhage.
d. Suppuration.
e. Deposition.

a. Thickening of the submucous tissue is the most frequent consequence of irritation of the mucous membrane; the calibre of the ducts is in this way diminished; actual stricture and obliteration of the tubes occurs, and the bile, at first but partially impeded, becomes altogether obstructed. The gall-bladder is sometimes enormously thickened, particularly where the irritation is kept up by the presence of several or a single large gall-stone. The coats are usually very much condensed and contracted, and their structure appears lost; occasionally they are dilated. In a case which occurred to Amussat,* wherein the ductus communis choledochus was obliterated, and the gall-bladder and ducts were very much distended, the middle coat presented all the characters of muscular fibres.

b. Softening of the mucous membrane may occur in the biliary ducts, but more particularly in the gall-bladder, and from the same causes which produce it in other mucous surfaces. I have seen two instances in the gall-bladder in which patches of the surface were converted into a softened pulp, which gave way upon the distension of the sac with air.

c. Hæmorrhage.—The gall-bladder has been observed filled with blood, having its source in the capillaries of the mucous membrane. In these cases intestinal hæmorrhage had occurred before death, and upon examination, no congestion or lesion could be found in the mucous membrane other than that which was seen in the gall-bladder.

d. Pus has likewise been found in the gall-bladder, and in the larger hepatic ducts, sometime pure, but generally mingled with the bile.

e. Abnormal *deposits* in the submucous cellular tissue are occasionally seen. They are most frequent in the gall-bladder, and consist generally of calcareous accretions.

3. *Disorders of the venous circulation.*—Under this head I have to describe the various forms of congestion of the liver. It has been customary hitherto to consider hepatic congestion as a pathological condition, and in compliance with that custom I have given it a place under the above title, although I shall have occasion to shew that it is not in itself a disease, but the mere result of diseased actions occurring in other parts, and wholly dependent upon the peculiar anatomical structure of the organ. Andral, in his excellent work on pathological anatomy, observes, "L'hyperémie du foie est un des états morbides que présente le plus fréquemment cet organe. Tantôt cette hyperémie est générale, alors le foie est partout d'un rouge uniforme; son volume est augmenté et sa consistance peu changée, lorsque l'hyperémie est simple. Cette hyperémie est souvent partielle; alors, en un certain nombre de points, on trouve comme des taches rouges variables en forme et en grandeur, qu'entoure un parenchyme plus pâle.

"Trois espèces d'hyperémie du foie doivent être admises, relativement aux conditions de l'économie dans lesquelles elles surviennent.

"Une première espèce d'hyperémie est celle

* Dictionnaire de Médecine, article Foie. Mr. Kiernan was the pupil of Amussat at this period, and saw this interesting case. He informs me that the appearance was distinctly muscular.

qui résulte d'un travail d'irritation dont le foie est devenu le siége. Cette irritation est tantôt idiopathique, et tantôt elle est la suite d'une irritation primitivement fixée sur le tube digestif.

"Une seconde espèce d'hyperémie, dont le foie me parait susceptible, est celle dans laquelle le sang s'accumule d'une manière toute passive au sein du parenchyme hépatique, comme il s'accumule dans les gencives des scorbutiques.

"Enfin le troisième espèce d'hyperémie du foie est purement mécanique; elle s'observe dans les cas où un obstacle quelconque s'oppose à la libre entrée du sang dans les cavités droites du cœur; le sang stagne alors dans les veines sus-hépatiques, et *engorge* le foie."

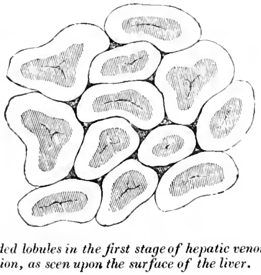
Now the researches of Kiernan have proved that "in consequence of its double circulation, the liver is naturally in a state of sanguineous congestion" after death, and that author has also pointed out the various forms of congestion which are observed in the organ. "Sanguineous congestion of the liver," he observes, "is either general or partial."

a. General congestion affects the whole of the substance of the liver, which presents a generally diffused red colour; the central portions of the lobules having usually a deeper hue than the marginal portions.

Partial congestion is of two kinds,
Hepatic venous congestion.
Portal venous congestion.

b Hepatic venous congestion may exist in two stages. "In the first and most common stage (*fig.* 42) the hepatic veins, their intralobular branches, and the central portions of the lobular venous plexuses are congested. The congested substance is in small isolated patches of a red colour, and occupying the centres of the lobules is medullary; the non-congested substance is of a yellowish white, yellow, or greenish colour, according to the quantity and quality of the bile it contains; it is continuous throughout the liver, and forming the marginal portions of the lobules is cortical."

Fig. 42.

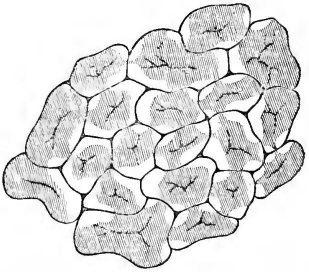


Rounded lobules in the first stage of hepatic venous congestion, as seen upon the surface of the liver. After Kiernan.

"This is the usual and natural state of the organ after death," and arises from arrest in the circulation of the hepatic veins, while the current of blood in the minute branches of the portal vein is still in motion.

"In the second stage (*fig.* 43) the congestion extends through the lobular venous plexuses to those branches of the portal vein situated in the interlobular fissures, but not to those in the spaces, which being larger there and giving origin to those in the fissures, are the last to be congested; when these vessels contain blood the congestion is general, and the whole liver is red. In this second stage the non-congested substance appears in isolated circular and ramous patches, in the centres of which the spaces and fissures are seen. This form of congestion "very commonly attends disease of the heart and acute disease of the lungs or pleuræ; the liver is larger than usual in consequence of the quantity of blood it contains, and is frequently at the same time in a state of biliary congestion, which probably arises from the sanguineous congestion. Although in the first stage the central portions of the plexuses, and in the second the greater portion of each plexus, and those branches of the portal vein occupying the fissures are congested, and although the plexuses are formed by the portal vein, yet as this form of congestion commences in the hepatic veins and extends towards the portal vein, and as it is necessary to distinguish this form from that commencing in the portal vein, the term of hepatic-venous congestion will not probably be deemed inapplicable to it." The second stage of hepatic venous congestion, generally combined with biliary congestion, gives rise to those various appearances which are called dram-drinkers' or nutmeg liver.

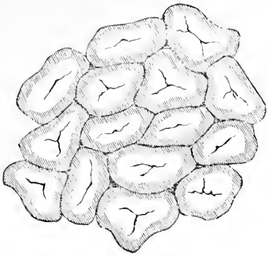
Fig. 43.



Lobules in the second stage of hepatic venous congestion, as seen on the surface of the liver. The dark centres of the preceding stage have become conjoined at the interlobular fissures, while the uncongested parts encircle an intralobular space.

c. "Portal venous congestion is of very rare occurrence; I have seen it in children only. In this form, the congested substance never assumes the deep red colour which characterises hepatic-venous congestion; the interlobular fissures and spaces and the marginal portions of the lobules are of a deeper colour than usual; the congested substance is continuous and cortical, the non-congested substance being me-

Fig. 44.



Lobules in a state of portal venous congestion, as seen on the surface of the liver. The congested part occupies the margins of the lobules, the uncongested portion their centres. After Kiernan.

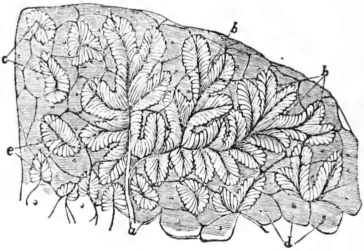
dullary and occupying the centres of the lobules."

The causes of congestion are all such as tend to interfere with the circulation in the liver or with the general circulation; for instance, impediment to the circulation of the blood through the capillaries of the lungs, diseases of the valves of the heart, aneurism, &c. A slighter degree of obstacle produces congestion of the hepatic veins only, the venous turgescence being limited by the lobular venous plexus. If the obstruction be greater, the lobular venous plexus itself is congested; if the cause continue, the congestion extends through the interlobular fissures into the neighbouring lobules, and in a more advanced degree the congestion spreads itself throughout the whole of the lobules, and becomes general. From the liver the congestion extends to the alimentary canal, and gives rise to intestinal hæmorrhages, hæmorrhoids, ascites, &c.

The variety of appearance in the vascularity of the lobules in congestion, and the constancy of its occurrence, have deceived those pathologists who maintain the existence of two substances, and the difference of position and form of the congested and uncongested portions has given cause for the diversity of opinion with regard to its situation. For a perfect elucidation of these difficulties, physiology is indebted to the genius and perseverance of Kiernan. The mode in which the attention of this author was drawn to the subject forms part of the history of hepatic congestion, and deserves to be detailed in his own words. "My attention," he observes, "was first directed to the anatomy of the liver by the study of the admirable works of M. Andral. In the first organs I examined I found the small branches of the hepatic veins ramifying exclusively in the red, and those of the portal vein in the yellow substance. I concluded that the liver was composed of two venous trees, a portal and an hepatic tree, the former having a cortex of yellow, the latter of red substance; and with M. Bouillaud, I thought it probable that the red substance was the organ of the function imagined by Bichat. I next ascertained the lobular structure, and concluded with Ferrein, that the red substance was medullary and the yellow cortical. Subsequent dissections, in which I found branches of both the portal and hepatic veins ramifying in the red substance, tended to unsettle the opinions I had formed respecting the anatomy and physiology of the two substances, and these opinions were finally overturned by the examination of a liver in which I found the branches of the portal vein alone ramifying in the red, and those of the hepatic veins in the yellow substance. The only conclusion that could be drawn was, that the red colour resulted from congestion; that it was medullary, occupying the centre of each lobule, when the hepatic, and cortical forming the circumference, when the portal vein was congested."

Müller, in the eleventh figure of plate 11 of his admirable work on the glands, has made a singular error with regard to the structure of the liver, and the arrangement of the ultimate biliary ducts. In the description of this figure he says, "Segmentum hepatis Sciuri junioris, microscopio simplici visum. Observantur fines ductuum biliferorum elongati, seu cylindri-

Fig. 45.

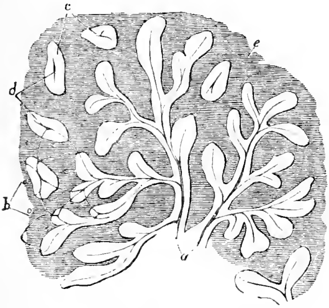


A part of Müller's 11*th figure of plate* 11, *which he considers to represent the distribution and arrangement of the ultimate biliary ducts. The liver in this section is in a state of hepatic venous congestion in the second stage. The congested portion corresponds generally with the central or hepatic part of the lobules, and the uncongested portion with the interlobular fissures, in which are situated the branches of the portal vein.*

a, A small branch of the portal vein giving off twigs to the various interlobular spaces. If these twigs be continued so as to unite with each other, the form of the lobules will be apparent; as at *b*, *b*. The angles formed by the giving off of the twigs from the portal vein are the interlobular spaces. *c*, Irregularly oval patches of uncongested lobules; the dark spot in the centre is an interlobular space, from which the portal vein radiates in various directions, so as to surround the various lobules by whose conjunction the space is formed. *d*, *d*, Lobules entirely congested. In the centre of the lobules of this section I have marked the situation of the intralobular vein, although it may not be apparent, or but slightly so, in the congested liver. The small spaces, *e*, *e*, generally mistaken for intralobular veins in this form of congested liver, are interlobular spaces.

formes acini, in figuris ramosis et foliatis varié dispositis." Now the truth is, that this section is in the second stage of hepatic venous congestion, and the "figuris ramosis et foliatis" are simply the uncongested portions of the lobules, of a lighter colour than the rest, and presenting the foliated and ramous appearance which is common to this form of congestion. The "fines ductuum biliferorum elongati seu cylindriformes acini" are obviously imaginary. The dark lines in the centre of the foliated ramifications are small branches of the portal vein lodged in interlobular fissures. If the twigs given off by these branches be made to unite with each other, we shall then have the true form of the lobules. This has been done in *fig.* 45, upon a part of Müller's drawing, for the purpose of shewing how the error has arisen, and how the form of the lobules may be restored. This appearance of the congested liver is by no means unfrequent in occurrence, and I subjoin a careful and accurate drawing of a similar arrangement in the human liver, (*fig.* 46,) for the purpose of comparison with that of Müller.

Fig. 46.



Section of a portion of liver exhibiting hepatic venous congestion in the second stage, carefully delineated from nature by Bagg, and intended to be compared with Müller's figure.

a, The portal vein in an interlobular fissure, giving off small twigs to adjoining fissures, and surrounded by the uncongested portion of the liver. *b,* The form of a few of the lobules is shewn. *c,* Irregular patches of uncongested liver, as in Müller's figure; the space in the centre of each being an interlobular space. *d,* Interlobular spaces. *e,* The congested portion of the liver.

Coming from so high an authority as Müller, this figure has been copied without hesitation by several writers, together with the explanation given of it by the author. Mr. Grainger has introduced it into his article upon the glands in this Cyclopædia, *fig.* 217, page 485, and Mr. Carpenter has also given it a place in his recent excellent work * on physiology. In his text, the latter gentleman observes with regard to the figure:—"In the squirrel indeed these prolongations may be distinctly seen, the blind sacs being cylindrical in form, and closely packed together."

Hepatic venous congestion in its most common form, viz., in the second stage, is the great stumbling-block of all anatomists who have engaged in the investigation of the minute anatomy of the liver; and it is under this head that I must now consider the views of Cruveilhier with regard to the supposed normal anatomy of this organ. Isolated from the distribution of the vessels in the liver, he has described the form and arrangement of the lobules with sufficient accuracy; but then it must be remembered that his description was written subsequently to the publication of the researches of Kiernan. But his conception of the structure of the lobules is completely erroneous, for after combating the common error of the existence of two distinct substances, he says:—"Les deux couleurs jaune et brune quand elles existent, n'appartient pas à deux granulations distinctes, mais bien à la même granulation qui est jaune au centre, où se trouve le bile, et rouge-brun à la circonférence, où se trouve le sang." Now Kiernan has distinctly proved that the structure of the lobules is the same throughout, and their colour is also uniform. Cruveilhier must therefore have founded his opinion and his description upon a liver in the second stage of hepatic congestion, in which there exists a delusive indication of lobules having the appearance of small oval and variously shaped patches, of a yellowish colour, situated at regular intervals, and surrounded by a reddish brown substance. These yellowish spots are seen in *figs.* 43, 45 & 46. They are the clusters of terminal biliary ducts of Müller,—the central portions of the lobules of the liver of Cruveilhier; but if they be examined carefully, their true nature will become clearly apparent. They are actually the *uncongested portions of the lobules of a liver in the state of hepatic venous congestion* at the second stage, and have each an interlobular space for a centre. In the next passage Cruveilhier observes:—"Le foie humain, excepte dans les cas de *dévelopment considérable* des granulations, se prete difficilement à leur etude vu leur petitesse." Here again in the words "dévelopment considérable," we perceive an idea founded upon the same erroneous impression with regard to the structure of the lobules. The real lobules are as nearly as possible of the same size in the liver of every individual, but these imaginary lobules of Cruveilhier, having uncongested portions of the hepatic substance for centres, necessarily vary in size and form with the degree of congestion, and hence have given rise to the idea of an increased development of the lobules. Again, the true lobules are not so small in the human liver as to render their examination difficult; they may be seen distinctly with the naked eye, and with the commonest lens may be examined accurately. But in the congested

* Principles of General and Comparative Physiology, 1839.

state of the organ they are more obscure, as may easily be inferred when we perceive such distinguished authorities as Müller and Cruveilhier, from want of making the liver the subject of especial investigation, deceived by such appearances. That Cruveilhier has actually mistaken the uncongested patches seen on the surface of a congested liver for the lobules, is clearly proved by a succeeding paragraph :—"Du reste, le volume des grains glanduleux présente beaucoup de variétés suivant les individus, et ce volume est tout-à-fait indépendant du volume du foie lui-même. Les médecins qui s'occupent d'anatomie pathologique ont souvent noté ce dévelopment, sous le titre d'hepar acinosum. Il est une maladie caractérisée par la coincidence de l'atrophie du foie, qui est réduit à la moietié, au tiers de son volume, et du dévelopment considérable des grains glanduleux." Now the hepar acinosum is without question a liver in the second stage of hepatic venous congestion, and presents several varieties in the precise form of the uncongested patches.

Starting with erroneous data such as these, what can be expected as the result of an experimental injection of the liver made by Cruveilhier, those who are thoroughly informed upon the exact anatomy of this organ will have no difficulty in anticipating; but to those who are only imperfectly acquainted with it, his conclusions must appear startling :—"Le foie ainsi injecté soumis à divers agens chimiques a présenté les resultats suivans: 1, l'injection bleue, c'est-à-dire celle de la veine cave, avait pénétré dans la partie centrale des grains glanduleux, partie qu'on appelle substance jaune du foie. Au milieu de la partie centrale était l'injection jaune, c'est-à-dire l'injection du canal biliare. Autour de l'injection bleue, etait l'injection rouge, c'est-à-dire, l'injection de la veine porte, et de l'artère hépatique, qui occupait toute la substance dite rouge du foie. Il suit de là que chaque grain glanduleux présente un appareil vasculaire ainsi disposé: 1, au centre, un canal biliare; 2, sur un plan plus excentrique, un cercle vasculaire formé par les ramifications de la veine hepatique; 3, un cercle vasculaire concentrique au précédent, formé par les ramifications de la veine porte et de l'artere hepatique." Thus in the centre of *his* lobule, Cruveilhier* found the yellow colour of the ducts, most probably effused and colouring the whole of the yellow portion of his lobule. Next came a circle of blue, and then a circle of red, formed conjointly by the portal vein and hepatic artery. Now we have shewn that the centre of Cruveilhier's lobule is an uncongested patch formed by the contiguous margins of several adjoining hepatic lobules, and having an interlobular space for a centre;—where, therefore, could we expect to find the yellow but in the interlobular space, and diffused immediately around it, so that the colouring matter would obscure the red injection of the portal vein and artery of that immediate point. Around the uncongested patch and in the congested substance we should find the intralobular veins of three or four or five surrounding hepatic lobules, (hence the variable size of Cruveilhier's lobules,) embracing by a kind of zone the yellow centre; and externally to the vein, the surrounding interlobular fissures would display the red injection of the portal vein and hepatic artery.

* These injections were not made by Cruveilhier himself, but by his assistant M. Bonami, as we are informed by M. Dujardin, in his paper "sur le foie, &c." The material used for the purpose was spirit varnish, and the results were not always successful.

4. *Disorders of biliary excretion.*—Biliary congestion may be produced by various causes; the most frequent is temporary thickening of the mucous lining of the ducts from inflammation or capillary congestion; this will simply diminish the calibre of the ducts or produce a complete stricture. The obstruction may endure for a shorter or longer period; the swelling of the membrane may subside and the tube be restored to its original dimensions, or it may become chronic and be a permanent impediment to the free current of the bile. Another cause of congestion of the bile-ducts is hepatic venous congestion, which acts by producing pressure upon the lobular biliary plexus and interlobular ducts. This is usually a chronic cause. Congestion of the bile-ducts may likewise depend upon the impaction of a gall-stone in the larger biliary ducts or ductus choledochus, obliteration of one of the ducts by the pressure of a tumour, disease of the pancreas, or thickening of the mucous membrane of the duodenum. In each of these cases the ducts are loaded with bile, which gives a yellowish or greenish hue to the whole substance of the liver. Biliary congestion in a chronic form is usually accompanied with more or less of hepatic venous congestion.

When one of the bile-ducts is obliterated or obstructed by a biliary concretion, the ducts become dilated above the constriction, and considerable reservoirs are formed in the substance of the organ. If the impediment exist in the ductus choledochus, the gall-bladder becomes greatly distended as well as the biliary ducts. The irritation caused by the pressure of the bile has given rise to inflammation and ulceration of the coats of the gall-bladder or of the ducts, and the bile has been effused into the peritoneal cavity and produced death. When the cause of the obstruction is a biliary calculus of moderate size, the pressure of the column of the bile will sometimes force it onwards into the duodenum, and thus remove the impediment. In other cases, when the obstruction occurs in the cystic duct, the bile ceases to enter the gall-bladder, the sac becomes thickened and diminished in size, and filled with a colourless viscid mucus.

5. *Diseases of the parenchyma.* — The diseases of the substance or parenchyma of the liver may be referred to the following heads:—*a*, inflammation; *b*, hypertrophy; *c*, atrophy; *d*, softening; *e*, induration; *f*, fatty degene-

ration; *g*, pus; *h*, tubercle; *i*, scirrhus; *k*, medullary sarcoma; *l*, fungus hæmatodes; *m*, melanosis.

a. Inflammation.—The tissue of the liver is liable to inflammation,—hepatitis, or the lobular hepatitis of some writers. The symptoms, like those detailed in the consideration of inflammation of the serous membrane, are severe and prominent, and clearly indicative of the nature of the disease. The pathologic appearances are deep redness, softness, general congestion, and enlargement of the organ from distension with blood. This condition is but rarely observed, from the circumstance of inflammation of the liver having no direct tendency to cause death, but being rather the precursor of the various other forms of disease which affect the organ. All the changes which occur in the liver are preceded or accompanied by inflammation acute or chronic, but more frequently by the latter, and in most instances by derangement of the venous circulation, and, occasionally, of the biliary excretion, giving rise to a complication of venous and biliary congestion.

b. Hypertrophy of the liver is increase of bulk of the organ, not depending, as in congestion, upon the quantity of blood circulating through it, but upon actual augmentation of the tissues of which it is composed. This state of enlargement of the liver may be general, or it may be confined to a part, as to a single lobe. Its predisposing cause is probably irritation of the mucous membrane of the ducts which gives rise in the first instance to retarded circulation and venous congestion, or it may be impediment either in the circulation through the heart, or through the rest of the venous system; or, again, it may depend upon diminution of the general powers of the system, as in a scrofulous constitution. The lobules are always in a state of partial congestion, resembling the second stage of hepatic venous congestion; the congested portion presents a deep red tint, and the uncongested part is ramose or convoluted in appearance, of a dirty white, greyish, yellowish, or greenish hue, in proportion to the condition of the biliary apparatus and to the quantity of bile contained within the liver. Sometimes the organ is pale, and appears deficient in its supply of blood; at other times it has a generally diffused redness, or the congestion may be greater in some situations than in others. The consistence of the liver in hypertrophy is equally variable with its colour: sometimes it is softer than natural, at other times it is dense and apparently granulated, the uncongested part projecting from the surface, and the congested portion sinking beneath its level. Hypertrophy of the liver is generally associated with chronic disease of the lungs, scrofula, and rickets, and often exists as a cause in ascites. It has been observed fifteen, eighteen, thirty-five, and even forty pounds in weight, and to have produced the displacement of the other abdominal viscera by its enormous size.

c. Atrophy of the liver is a condition of the nutritive functions of the organ which may succeed chronic inflammation or even hypertrophy; it occurs more rarely than hypertrophy, to which its comparative frequency has been estimated by Portal as 5 to 95. The substance of the liver diminishes in bulk, the lobules become indistinct and variously congested, and they appear intermingled and pressed upon by the cellular structure with which they are surrounded. Sometimes the proper structure of the liver is entirely removed and replaced by a loose or condensed cellular tissue. At other times the entire substance of the organ appears to have been absorbed by an enormous abscess, which has evacuated its contents into the intestinal canal, and the parietes have afterwards contracted and degenerated into an atrophied mass. Lieutaud gives an account of a liver that was shrivelled into a mass not larger than his fist. Portal found the liver in a case of ascites not bigger than an apple of ordinary size. Partial atrophy of the liver conjoined with hepatic venous congestion is not an infrequent consequence of the practice of tight lacing. I have before me a very interesting specimen of this affection. The surface of the liver is marked by deep fissures into irregular polygonal divisions resembling very strikingly the lobulated appearance of the fœtal kidney. In one situation the stages of this change are distinctly apparent; a certain portion of the organ, about half an inch in breadth, has become partially atrophied from the pressure of two adjoining and protuberant portions of the liver, and in the lobulated portion the hepatic substance of this atrophied mass has been completely removed by absorption, leaving a kind of condensed cellular cicatrix extending like a septum for some distance into the organ. It is in this way that many of the grooves and fissures upon the convex surface of the liver are formed.

But the most interesting form of atrophy of the liver is that which was named by Laennec cirrhosis. In cirrhosis, the liver is diminished in volume to the extent of one-half or one-third of its natural bulk, the relative size of the right and left lobes is destroyed, and the surface is rendered shapeless by the projection of a number of ridges or granular points. The entire organ appears wrinkled and shrivelled, and of a yellow or greenish colour, varying in tint from a bright chrome to a yellowish or greenish brown. Upon dividing it with a knife it is observed to be more dense than usual, and the surface of the section presents a number of patches of variable size and of a roundish form, which resemble granules; hence this condition of the organ is named by the French authors " foie granuleux." In an advanced stage it is accompanied with jaundice and ascites, and is frequently preceded by some disease, either of the lungs or heart.

Kiernan is, I believe, the first pathologist who distinguished the true nature of cirrhosis, which he called *atrophy of the liver*. A very interesting case of this disease occurred in St. Bartholomew's Hospital, under the care of Dr. Latham, in 1832, an account of which was published in the *Lancet* in November of that year. The patient died with jaundice and ascites. The liver, a portion of which I possess, presented a fine specimen of granulated cirrhosis; it "was diminished to one-half its natural size, and Mr. Kiernan on injecting it, discovered that a *collateral venous circulation had been established by way of the diaphragm.*" In another case in a woman who had been tapped ninety times, Kiernan upon injecting the liver found that the same kind of collateral circulation had been formed. The circulation through the liver had been impeded by the developement of condensed cellular tissue, and the greater part of the blood of the portal vein had made its way through dilated vessels upon the surface of the organ to the diaphragm, and from thence into the general venous circulation. In this case there were numerous bands of adhesion between the liver and diaphragm, and between the intestines and the walls of the abdomen, and these also were traversed by large veins conveying blood from the portal vein into the general venous current.

With regard to the pathological nature of the disease many opinions have been entertained by different writers. Laennec, dazzled by an ingenious theory deduced from his observations upon the nature and progress of scrofulous tubercle, saw in the mottled and granular section of cirrhosis only a "morbid deposit," a special accidental tissue existing in the two states of crudity and softening. But I quote the words of this author as detailed by Ferrus,* for while he errs in his speculations with regard to the nature of the disease, he draws an excellent picture of its general characters and appearance. "Les cirrhons existent dans l'état de crudité et de ramollissement. Dans le premier de ces états elles présentent un tissu d'une couleur fauve plus au moins foncée, qui quelquefois tire un peu sur le verdâtre; on ne peut s'en faire une meilleure idée qu'en la comparant à celle qu'offrent les capsules surrénales chez l'adulte. Ce tissu, quoique fort consistant, a une sorte de flaccidité que je ne puis mieux comparer qu' à celle de certains fongus, ou d'un cuir mou. Le tissu des cyrrhoses est d'ailleurs compact, assez humide et très-délié. On n'y distingue aucune trace de fibres, quoiqu'il presente en certains cas des divisions en forme de squames. Les cyrrhoses prennent en se ramollissant une couleur plus brunâtre."

"M. Laennec admet trois sortes de cyrrhoses: 1°. cyrrhoses en masses; 2°. en plaques; 3°. en kystes. Lorsqu'il existe, dit-il, des cyrrhoses dans le foie, elles forment ordinairement de petites masses dont le volume ne surpasse jamais celui d'un noyau de cerise, et quelquefois égale à peine celui d'un gros grain de millet. Ces masses sont toujours extrêmement nombreuses, et tout le tissu du foie en est parsemé. Leur petitesse fait que lorsqu'on incise un foie dans lequel il en existe un grand nombre, son tissu paraît au premier coup d'œil homogène et d'une couleur jaune fauve. Mais si on examine plus attentivement le tissu hepatique, on s'aperçoit facilement qu'il est rempli d'une innombrable quantité de corpuscules assez semblables, pour l'aspect à ces lobules de graisse durcie et rousseâtre que l'on trouve communément dans le tissu cellulaire sous-cutané de la cuisse et de la jambe des sujets attaqués d'anasarque. Ces petites masses sont quelquefois unies très-intimement au tissu du foie; mais assex souvent elles en sont separées par une couche mince de tissu cellulaire qui leur forme une enveloppe tenue, et alors ils se détachent assez facilement. La surface extérieure du foie devient flétrie, rugueuse, et ratatinée à-peu-pres de la même manière qu'une pomme flétrie."

Bouillaud* considers this condition of the liver a dissociation of the two natural elements of the organ: "les masses jaunes fauves constituant le tissu accidentel, appelé cirrhose, ne sont autres chose que les granulations secretoires se desorganisant graduellement par l'effet de l'obliteration du lacis vasculaire, et de l'obstacle à la circulation hepatique qui en resulte." We have already combatted the existence of two substances, and further remark upon this subject must be quite unnecessary.

Andral † sees, in the cirrhosis, atrophy of the red substance and hypertrophy of the yellow substance. Of all modern authors, Cruveilhier approaches nearest to the true condition of the organ, but from his misapprehension of the exact nature of the lobules, even his opinion cannot be accepted without limitation. Cirrhosis, says this author,‡ is "atrophie du plus grand nombre des grains glanduleux, et hypertrophie avec coloration jaune des grains glanduleux restans." Now cirrhosis is undoubtedly a partial atrophy of the liver with hypertrophy of the cellular structure; complete atrophy of some of the lobules, partial atrophy of others, and biliary congestion without atrophy or hypertrophy of the rest. Those small yellow grains varying in size from a millet-seed to a pea or to a hazel-nut, are not distinct lobules in a variable state of hypertrophy, but small uncongested patches composed of parts of several adjoining lobules, and having a single or several interlobular spaces for a centre. Hence it is, as we have before shown, that Cruveilhier § has observed the "partie centrale de chaque granulation repond au radicule biliare, et consequemment est souvent teinte en jaune et que la partie excentrique repond à l'element vasculaire et consequemment est plus rouge que la partie centrale."

d. Softening of the liver may accompany any of the changes resulting from acute inflammation. The degree of softening is very variable, the organ having at one time a simple abnormal degree of friability when pressed by the hand, and at others constituting a pulpy mass scarcely retained in its form by the cellular framework of its vessels and Glisson's capsule. Softening may be unaccompanied by any marked change in the bulk of the organ, but is always associated with a variable intensity of venous congestion. Biliary

§ Anatomie Pathologique, livraison 12.

congestion is also frequently present, and tinges the substance of the organ with a variable hue of yellow, green, &c. Portal observes that the liver of patients who have died of scurvy is often so much softened that it appears in a state of decomposition, has a reddish brown colour, and resembles the lees of red wine. Baillie remarks that softening of the liver is not uncommon in old persons, that it approaches in consistence to the texture of the spleen, and is of a brownish red colour.

e. Induration of the liver is occasionally attendant upon hypertrophy or atrophy of the organ, but it may also exist with a normal size of the liver without other apparent change than the brownish red tint which it receives from venous congestion, or the various shades of yellow, green, or brown induced by biliary congestion. The density and hardness acquired by the liver in a state of atrophy are sometimes truly astonishing. In a case detailed by Morgagni the organ resisted the knife, and several such instances are to be met with among the writings of the older pathologists.

f. Fatty degeneration of the liver.—Upon referring to the section upon the chemical analysis of the liver, it will be observed that a certain proportion of oily matter is one of its natural constituents. Under the influence of diseased action this quantity is greatly augmented, and increases to such an extent as completely to take the place of the normal structures. Vauquelin has published an analysis of a fatty liver, from which the quantity of oily matter present may be fairly estimated thus; in 100 parts he found,

Oil	45
Parenchyma	19
Water	36
	100

The fatty matter is usually distributed equally through the organ, being apparently infiltrated into the cellular texture of the parenchyma. At other times it is deposited in a mass or forms several collections in different parts of the liver. The fatty liver is greasy upon the surface, and when cut into has the appearance of a section of yellow soap. The vessels seem pressed upon and are scarcely perceptible, while the greasy deposition is divided into angular masses by a coarse and compressed cellular tissue.

Fatty liver is generally consistent and solid in its texture, but sometimes the fat exists almost in a fluid state. Portal has observed the liver quite white and softened almost to the fluidity of melted fat, where no hepatic symptoms existed during life; and he particularly records the case of a woman suffering under a severe form of syphilis in which this condition of the liver existed.

From the name which has been given to this disease by pathologists, *fatty degeneration*, we might be led to infer that the texture of the organ was actually converted into this oily substance. This, however, is quite inconsistent with our knowledge of pathological phenomena. The fatty deposition is obviously an undue secretion of a normal constituent, but whether resulting from irritation from whatever cause, or from absence of vital energy, is a question upon which I am unwilling, without further investigation, to hazard an opinion. With regard to the causes of fatty liver Andral observes, " Les causes sous l'influence des quelles le foie devient le siége d'une sécrétion de matière grasse sont encore inconnues. On n'a émis qu'une hypothèse lorsq'on a dit que la dégénération graisseuse du foie était le produit d'une irritation de cet organe. Car on pourrait tout aussi bien soutenir que cette dégénération graisseuse, loin d'avoir été précédée par un état d'irritation du foie, est survenue parceque la nutrition de cet organe est devenue moins active; et cette dernière hypothèse serait d'autant plus soutenable, qu'elle se déduirait d'une grande loi de l'économie en vertu de laquelle, toutes les fois qu'un organe tend à s'atrophier, une matière grasse vient à se sécréter autour de cet organe ou à la place même de ses molécules."*

Fatty liver is most frequently observed in persons who have died from scrofulous tubercles in the lungs; in those, says Andral, in whom the blood has not been efficiently arterialised, and in whom the pulmonary exhalation is greatly diminished. Can it be, he inquires, from the absence of the due separation of hydrogen from the lungs that this compound of hydrogen, fat, becomes deposited in the parenchyma of the liver? This question is well deserving the attention of pathologists, and its solution might lead to important information. The disease has also been observed in some cancerous disorders and in dartrous diseases of of the skin.

g. Pus. Abscess in the liver occurs in two principal forms, either as a single abscess of large size inclosed in a cyst, or as numerous small collections of matter, bounded by the substance of the liver or diffused amongst its lobules. In the first form it constitutes idiopathic abscess of the liver, a disease of tropical countries, and rare in our temperate climates. Abscess is generally preceded by acute inflammation and more rarely by chronic inflammation, and attains an enormous size, engrossing the whole of the right lobe and sometimes converting the entire organ into one huge cyst. The cyst may be thin or thick, and more or less organised. Andral and Louis conceive that its internal surface is analogous to a mucous membrane. The quantity of pus contained in one of these abscesses varies from a few ounces to several pints. My friend Dr. Macnaught, who has seen much practice in the West Indies during a residence of twenty-two years in Jamaica, has observed that abscess in the liver occurs more rarely in the West than in the East, and, moreover, that this disease affects the Europeans and not the Negroes. During the whole of his experience he never saw a single case of abscess in the liver in the Negro, and among the white population of his district only four well-marked instances.

* Anatomie Pathologique, vol. ii. p. 597.

The irritation of abscess causes the effusion of lymph and adhesion to the abdominal parietes or to the adjoining viscera; ulceration follows, and the contents of the cyst are discharged through the artificial opening. The situations in which the matter escapes from the cavity of the abscess are various. 1. It may burst externally, making its way either between the ribs or upwards towards the axilla. In a case observed by Dr. Macnaught the abscess pointed at the epigastrium and was opened by the surgeon in attendance. 2. It may become adherent to the diaphragm and burst into the pleura. 3. It may cause adhesion between the serous membrane of the liver and of the diaphragm, and between the latter and the pleura pulmonalis, and the matter may escape into the lung and be coughed up, as in the case already detailed, which occurred to Dr. Munro. 4. In rare cases the pus has been effused into the cavity of the peritoneum. 5. The abscess may become adherent to the stomach, duodenum, or colon, and the matter be discharged into the alimentary canal. A well-marked case of abscess discharging its contents into the stomach occurred to myself in the case of a woman who has since perfectly recovered. About two pints of matter were vomited by the patient. In a similar case observed by Dr. Macnaught the patient recovered. In two other cases, where the matter was poured into the intestines, the patients died. 6. Abscess has been seen to open into the gall-bladder, and the pus to be conveyed thence through the ductus communis choledochus into the duodenum. 7. In one case the matter was discharged into the vena cava; and in another, 8, described by Dr. Smith, into the pericardium; and in a case detailed by Dr. Graves,* the abscess opened both into the stomach and pericardium.

Besides the preceding form of abscess, which is idiopathic in its origin, abscess may occur in the liver from external injury, as from a blow. The inflammation attending upon this injury is much slighter than that which gives rise to idiopathic abscess; the collection of matter is generally smaller, and terminates either by discharging its contents or by absorption.

The second variety of abscess in the liver, that in which numerous purulent collections exist, depends for its cause upon the occurrence of wounds or of surgical operations. The succession of abscesses in the liver from wounds, particularly of the head, has long since been admitted as a well-established fact, for the explanation of which numerous theories have been invented. Theory, however, has now yielded before facts,—facts, too, of the most interesting and satisfactory kind, for which pathology is indebted to the genius and industry of Cruveilhier. The experimental researches † of this excellent author, published in 1826, enabled him to establish a law of the utmost importance in the consideration of the phenomena of disease, viz. that " tout corps etranger introduit en nature dans le systeme veineux determine lorsque son elimination par les emonctoires est impossible des abscès viscéraux entièrement semblables à ceux qui succèdent aux plaies et aux opérations chirurgicales, et ces abscès sont le resultat d'une phlebite capillaire de ces mêmes visceres."* These experiments consisted in the introduction of metallic mercury into the veins of an animal, say of the lower extremity. In the course of twelve, eighteen, or twenty-four hours the animal experienced much difficulty of breathing, and soon expired. Upon inspection globules of the mercury were found in the lungs. If a smaller quantity of mercury were introduced the animal would live for several days or weeks, and upon examining the lungs at different periods the globules were at first seen to be surrounded by a red induration and afterwards by pus. This experiment was varied by pouring the mercury into the medullary cavity of a bone with precisely the same results; in one instance he placed a single globule in the medullary cavity and found it again at the end of a month in the lungs, divided into several minute globules, each of which formed the centre of a small tuberculous abscess. Cruveilhier then injected a small quantity of mercury into one of the omental veins of a dog—the subject of umbilical hernia; the dog was killed in the third month after the operation, being reduced to a state of marasmus. Upon inspection the liver was found filled with small abscesses, each surrounding a small globule of mercury. Having by means of these experiments satisfied himself that the lungs were the barrier to all foreign matters introduced into the general circulation, as was the liver of those admitted into the abdominal circulation, he proceeded to another series of experiments. Opening a vein in the hinder extremity of a dog he introduced into it a long piece of stick, which gave rise to phlebitis and the secretion of pus. The pus thus produced being carried into the circulation excited, in the first instance, abscesses in the lungs, and, secondly, in the liver. Upon these facts and upon a multitude of excellent observations Cruveilhier founds his opinion that abscess in the liver from wounds and surgical operations is always preceded or accompanied by purulent collections in the lungs, and always results from the same cause, viz. from capillary phlebitis, consecutive upon phlebitis in the neighbourhood of the wound, and immediately produced by the irritative action of globules of pus brought from the diseased veins to the capillaries of the structures in which the secondary suppuration is developed.

In every case of secondary abscess in the liver, following wounds of the head, or after amputation or operations upon bones, Cruveilhier has found phlebitis of the vessels situated in the structure of the bones. Hence he establishes an important general proposition, that " le phlébite des os est une des causes les plus fréquentes des abscès viscéraux suite des plaies et des opérations chirurgicales dans

* Dublin Medical Journal, January 1839.

† Recherches sur la siege immed. de l'inflammation. Nouv. Bibl. Med. vol. iv.

* Anatomie Pathologique, liv. xi.

lesquelles ces os ont été intéressés." The removal of hæmorrhoids and operations upon the uterus are sometimes followed by abscess of the liver, a circumstance which is easily explicable upon the principles so clearly demonstrated by this author.

An excellent instance of secondary abscess of larger size than usual has been kindly furnished to me by my friend and colleague Mr. Rutherford Alcock, who, from his official position in Spain and Portugal during the recent struggles, has had much experience in injuries to the head. A man received a bayonet wound in the scalp, and died upon the fourteenth day after his admission into the hospital. Upon inspection there was observed thickening of the dura mater and a small quantity of matter upon the pia mater. No pus was discovered in the lungs, but a large abscess was found occupying the greater part of the right lobe. A statistical report from a work upon gun-shot wounds by the same author is also interesting. "Of scalp wounds, with and without abrasion, there were sixty-one; two only died, and one only presented disease of the liver; the other died from an attack of erysipelas."

The pathological changes which take place in the liver in these cases are, in the first instance, effusion of blood and lymph and induration around the inflamed vein; secondly, a secretion of a yellow concrete pus into the minute veins and among the lobules, giving to the liver, as Cruveilhier remarks, a granite-like appearance. In the next place the pus collects into small abscesses lodged in irregular cells, which increase in size by continued secretion and by communication with other cells. All these collections of matter are surrounded by a congested circle, which gives them a peculiar and characteristic appearance. After having existed for some time Cruveilhier has observed that the pus becomes converted into a concrete mass, very closely resembling the matter of scrofulous tubercle.

h. Tubercle in the liver is a disease of rare occurrence, and has seldom been observed independently of the existence of similar depositions in the lungs and other organs of the body, and of general indications of a scrofulous diathesis. When present, it exists in the form of small rounded tubercles, generally numerous, and varying in size from that of a millet-seed to a hazel-nut. They are composed of the soft cheesy or curdy deposit which is characteristic of this disease, and have a tendency to a brownish colour. The tuberculous matter is deposited in the tissue of the lobules by infiltration, and the lobules immediately surrounding the tumours are compressed and congested. The obstruction to the circulation in the organ being general on account of the number of the tubercles, the entire liver is more or less congested.

i. Scirrhus.—Carcinoma affects the liver under a variety of forms, but appears most frequently as tubercles of different size and consistence. These tubercles are more frequent than those of scrofulous origin, and are generally accompanied by symptoms denoting a cancerous diathesis, and by the existence at the same time of similar tumours in other parts of the body. In their earliest development in the liver nearly all carcinomatous tumours present the same characters, resembling small, whitish, semi-opaque patches, occupying the tissue of one or of several of the lobules. As they increase in size they put on certain peculiar appearances, which have gained for them a subdivision into species and varieties. I do not intend in this place to enter into the arrangements proposed by authors, but will briefly describe the most striking varieties that have fallen beneath my own examination. The simplest of these tumours has been termed *scirrhous tubercle,* a name which appears particularly applicable from its resemblance in characters and structure to the same form of tumour occurring in other parts of the body. Commencing like the carcinomatous tumour generally in a semi-opaque patch, the outline of the lobules is for some time distinctly perceptible through its area, but at a later period the centre of the patch becomes quite opaque, and presents a cartilaginous hardness and creaking sound when divided with the knife. The circumference is gradually diffused in the surrounding textures, and the progressive increase of the tumour seems to take place by the secretion of a milky albuminous fluid into the meshes of the lobular venous plexuses. The circulation in these plexuses is at first unimpeded, but by the increase and induration of the secretion it is gradually arrested, and the vessels obliterated The obliterated vessels give rise to the appearance of small cells, in which the carcinomatous matter is deposited, and the larger areæ are produced by the tissue of the capsules of the lobules variously distorted from their original form by the increased deposition. As the tumours become more and more large, white lines, formed by compressed cellular tissue, are observed radiating from the centre towards the circumference. When seen upon the surface of the liver, the scirrhous tubercle appears flat, or very slightly depressed towards the centre. In a preparation of this form of tubercle now before me, the whole tumour is slightly raised above the surface; it presents no central depression, is cartilaginous in appearance, and has an irregular outline. Its section is dense and hard like cartilage, with no appearance of vessels, and of that pearly and semitransparent whiteness which is generally observed in scirrhous tubercle, particularly in the variety which this preparation illustrates. Sometimes these tubera are small and very numerous, of a yellowish or brownish colour, and have a great activity of increase; the cells in which they are contained are thick and of larger size, and the albuminous secretion less firm than in the preceding variety. Occasionally they are reddened in the centre by the effusion of blood, from the congestion of unobliterated vessels, and sometimes by the continuation, through the tumours, of dilated vessels, which supply them with nutrition. In their enlarged state they frequently coalesce and give rise to an irregular compound mass, which assumes the form of the particular part of the organ in which it is placed, and is divided into compartments, marking its original multiple form by septa of condensed Glisson's capsule supporting dilated vessels. It would appear to be this form of tumour which has been described by Farre as the first variety of his tubera diffusa; he gives them the following character. "Tubera, elevated at the surface of the organ, but not uniform in their figure, some rising with a regular swell into a round form, others acquiring a margin by being gradually depressed towards the centre, forming tumours without cysts, almost pulpy in their consistence, cellular in their structure, and containing an opaque white fluid."

Another form of the albuminous carcinomatous tumour is the "large white tubercle" of Baillie, the tubera circumscripta of Farre, by whom they are thus admirably described: "Their colour inclines to a yellowish white, and their projecting surfaces, slightly variegated with red vessels, deviate from a regular swell by a peculiar indentation at or near their centres, which are perfectly white and opaque. They vary much in size, which depends on the duration of each tuber, for at its first appearance it is very minute, but during its growth it assumes the character above described, and at its maturity exceeds an inch in its diameter. They adhere intimately to the liver, and their figure is well defined. They commonly remain distinct at the surface of the liver, but internally they ultimately coalesce and form immense morbid masses which pervade its substance. They possess so close a cellular structure that the section of them at first view appears solid and inorganic; but on the edge of the knife, by which they have been dissevered, an opaque white fluid of the consistence of cream is left, and a fresh portion of this fluid is gathered on it at each time that it is repassed over the surface of the section. Their cellular structure becomes more apparent after long maceration."

The depression in the centre of carcinomatous tumours, although generally met with, is not a necessary character of cancer. Its mode of formation has been ably pointed out by Dr. Carswell, in his beautiful work on pathological anatomy: "The depression is not observed unless when the tumour is divided or is situated on the surface of an organ, as the liver, where tumours of this kind are generally met with. In the former case the depression arises from the softer substance, after the division of the tumour raising itself by its elasticity above the unyielding nucleus; in the latter it is produced by the peritoneum adhering to the surface of the tumour when small, and preventing its development in that direction. If the tumour does not come in contact with the peritoneum until it has acquired a considerable size, it presents no such depression, or only a very small one. Hence the reason why, in carcinoma of the liver, we meet with some tumours having a smooth globular surface, and others with a central depression of greater or less extent."

Another variety of carcinomatous tumour is named the gelatiniform cancer, from the existence of a firm and jelly-like deposit which occupies the cells of the tumour in place of the albuminous secretion common to the preceding forms. I have before me an interesting specimen of gelatiniform tubercle. The liver contains a considerable number of these tumours of variable size, and dispersed through every part of its structure. The smallest resemble the small patches described above as the incipient stage of carcinomatous tumour generally; the largest are equal in size to a walnut. They are distinctly circumscribed, and the lobules immediately surrounding them are flattened and compressed. In the smaller tubercles the form of the lobules is quite distinct, but in the larger the lobules have yielded to the peculiar characters of the disease. On the surface the centre of the tubercle presents an oval or circularly indented ring, around which the tumour swells suddenly and then subsides to the circumference. On making a section of one of these tumours, I found a central area of about two lines in diameter, transparent, dense, and apparently gelatinous, and distinctly bounded by a white marginal line; the marginal portion of the section forming the bulk of the tumour was elastic, and rose above the central area to subside gradually in the marginal line of the circumference. The whole section bore a striking resemblance to the conjunctiva affected with chemosis, only that it was paler in its colour, or to a beautiful flower with a single large and expanded circle of petals. On examining a thin section with a lens of low power a number of minute parallel injected capillaries were seen traversing the marginal portion of the tubercle towards the boundary line of the area, but no vessels could be traced beyond that line into the central portion. The resemblance to the petals of a flower was produced by white lines which radiated from the boundary line of the area to the circumference, and divided the marginal portion of the tumour into six or eight compartments. From careful examination it appeared to me that the central area was a single lobule expanded by the gelatinous deposition with which its tissue was infiltrated, and the marginal compartments presented a similar character.

k. Medullary sarcoma.—Another form of tubercle, associated with the cancerous diathesis and belonging to the carcinomatous family, is medullary sarcoma, or encephalosis. The tumours produced by this disease are larger than scrofulous tubercles, and more regular in form and fewer in number than scirrhous tumours. Developed originally in the same way with scirrhus, by infiltration into the tissue of the lobules, or into the vessels themselves, of the peculiar greyish white and opaque substance of which they are composed, they increase in size and obstruct the circulation in the surrounding lobules. Their internal structure is a loose cellular base, filled with a soft and brain-like matter, frequently coloured with blood, or containing coagula in various stages of softening, resulting from hæmorrhagic extravasation.

Sometimes these tumours present a certain degree of consistence, but as they increase in size they become more and more softened and pulpy. Baillie describes a large tumour in the liver which he considers scrofulous from being softened in the centre, and containing a fluid resembling pus; this is most probably a tumour of the kind I am now describing. Another tumour, of which he expresses himself at a loss to understand the nature, soft, of a brownish colour, and of about the size of a nut, appears to be also referable to the same species.

The second and third varieties of the tubera diffusa of Farre present characters resembling this disease. V. 2. "Tubera, elevated at the surfaces of the affected organ, encysted, or having distinct cells, formed by the growth of a fungus, which separates in flakes, and is composed of a fine reticular texture, containing an opaque white fluid." V. 3. "Tumours rising with a regular swell from the surfaces of the affected parts and yielding to the touch, composed of a very delicate reticular texture, pulpy in its consistence, varying in its colour even in the same subject, charged with an opaque fluid, and growing from cysts or cells."

Cruveilhier considers the venous capillary system as the seat of origin of carcinoma, particularly of the form which I am now considering; hence he observes, "Ayant exprimé d'une coupe faite à un foie cancéreux une matière d'un blanc-rougeâtre, encéphaloïde qui se moulait à la manière du vermicelle, et qui pouvait acquérir en se tordant une grande longueur, j'aperçus sur cette coupe un orifice plus considérable que les autres; j'incisai cet orifice et je parvins dans un vaisseau très volumineux qui me parut être une des ramifications de la veine porte. Alors je disséquai avec beaucoup d'attention cette veine, et je ne fus pas peu étonné de voir que cette veine, depuis les plus grandes jusq'aux plus petites divisions, était remplie par cette matiere encéphaloïde, adhérente aux parois et tout-à-fait semblable à celle qu'on exprimait par les coupes faites au foie. Il me fut facile de suivre les ramifications extrêmement dilatées de la veine jusque dans l'areoles des coupes. L'altération était bornée à la veine porte, les veines hépatiques et leurs ramifications étaient parfaitement saines."*

l. Fungus hæmatodes is the term applied to all carcinomatous tumours which have a tendency to the unnatural development of new vessels and to effusions of blood into their tissue. In the same organ, hard and cartilaginous scirrhous tumours may exist with those of a softer texture, and of a medullary form, and both of these may be mingled together in the soft, elastic, and bleeding mass which constitutes fungus hæmatodes. The tumours of fungus hæmatodes are often of very large size, and by their frequent hemorrhagies give rise to extreme symptoms and the speedy death of the patient. Farre arranges this form of carcinoma among his tubera diffusa, of which it forms the fourth variety, which he thus defines: "Tumours elevated at the surfaces of the liver and inclining to a round figure; pulpy in their consistence, being charged with a thick and opaque fluid, variegated in their colour, chiefly white mingled with red, the former prevailing in their incipient, the latter in their advanced stages, composed of a very vascular and reticular texture, attached either to distinct pouches or to the substance of the liver, and so unlimited and rapid in its growth as to burst or destroy the peritoneal tunic of this organ and to protrude in the form of a bleeding fungus."

m. Melanosis.—Melanosis exists in the liver, as in other structures of the body, 1st, as a melanic secretion infiltrating the cellular structure of the organ, and giving a diffused general blackness to the substance of the lobules; 2d, as a morbid tissue composed of an areolar cellular network, in which the black carbonaceous matter is deposited; or 3dly, as a melanic pigment accompanying carcinoma or tubercle, and imbuing the abnormal tissue with its peculiar colour. The colour of melanosis in the liver varies from a deep chocolate-brown to a rich black. Sometimes it is diffused in patches through the substance of the organ, at other times it exists in the form of rounded circumscribed tubercles of variable size and number. Laennec considers melanosis as an accidental tissue without analogue among the animal tissues; he classes it with cancerous degenerations, and describes it as existing in his two favourite conditions of crudity and softening. But the researches of Cruveilhier have shewn that in many instances melanosis is to be received as a mere pigment, resembling the pigmentum nigrum of the choroid, which impresses its peculiar colour upon natural and morbid tissues, and he has also proved, in opposition to the view entertained by Laennec, that the softened state or state of infiltration very frequently precedes the more dense and encysted form. Melanosis rarely exists in the liver without being at the same time found in various other structures of the body, as in the brain, eye, lungs, heart, spleen, kidney, mucous membrane, muscles, skin, &c.

6. Disorders of function.—The principal function of the liver being the secretion of bile, we shall have to consider under this head the changes which may occur in the secretion of this fluid and in the fluid itself, in consequence of derangement of function in the organ. These disorders may be divided into three kinds:—

a. Suppression of the bile.

b. Alterations in the physical properties of the bile.

c. Alterations in the chemical qualities of the bile.

a. Suppression of secretion of the bile, like suppression of urine, occasionally occurs in the liver. This disease appears to have been known to Darwin,* who calls it "paralysis of the secretory vessels" of the liver; the patients, he says, "lose their appetite, then their flesh and strength diminish in consequence, there appears no bile in their stools nor in their urine,

* Anatomie Pathologique, liv. 12.

* Zoonomia, vol. ii, p. 5.

nor is any hardness or swelling perceptible in the region of the liver." Kiernan, who has observed several cases of this disease, informs me that the symptoms are sudden jaundice, depression of the powers of the system, and speedy dissolution; upon dissection he found complete absence of bile in the biliary ducts, the mucous membrane of which appeared bleached.

b. Alterations in the physical properties of the bile.—The changes to which the bile is liable are in no wise referable to any particular alteration in the liver. In cases where this organ has been considerably diseased, the secretion of the bile has been found natural and healthy; and in other cases, where a slight degree of congestion was all the apparent pathological derangement, the secretion has assumed a morbid appearance, or has been deficient or superabundant in quantity. Gall-stones are sometimes found in the gall-bladder without any admonitory symptoms during life, and icterus may be a frequent and even a fatal malady without any obstruction appearing in the course of the biliary tubes after death, or without any satisfactory indications of diseased action in the liver. "I have been sometimes astonished," says Andral, "on seeing the enormous quantity of bile which distended the alimentary canal in cases where the slightest degree of congestion existed in its coats, and when the liver appeared in no wise altered." Nay, it has been proved both by observation and experiment that the bile is materially changed in appearance, quantity, and consistence by the mere alteration of diet. Experiments made upon living animals have long since shewn that bile taken from different individuals is capable of producing very different effects upon the animals into whose bodies it has been introduced; thus some will give rise to a trifling irritation, while others will occasion more or less serious symptoms and even rapid death. Some bile may be touched and even tasted without inconvenience, while other bile, precisely similar in appearance, will produce pustular eruptions and ulcerations upon the tongue and upon the lips. "Here then," says Andral, "are serious changes in the bile which are wholly imperceptible to the investigation of anatomy."

The colour of the bile differs very considerably, being sometimes hardly distinguishable from serum, and at other times presenting a variable tint of amber, orange, green, brown, olive, and even black. In consistence it is equally various, being one while limpid and diffluent, and another while black, viscous, and grumous.

b. Alterations in the chemical properties of the bile.—In chemical composition, the alterations in the bile are not less numerous than in its physical properties. In fatty liver the bile has been found composed almost wholly of albumen and water. Under other circumstances the natural constituents are greatly altered in their relative proportion.

The formation of biliary calculi may be referred to disproportionate secretion of the natural elements of the bile, the increased quantity of certain of its constituents giving rise to the deposition and accretion of these substances in a form corresponding with the cavities in which they are produced. Gall-stones have been found in the smaller biliary ducts in the substance of the liver, in the excretory ducts both within and external to the organ, and in the gall-bladder. They have also been met with inclosed in a cyst, formed most probably by the obliteration of one of the hepatic ducts, and adherent to the organ or suspended from it by a pedicle. Malpighi found gall-stones in the small biliary ducts and considered them as petrified lobules. The *size* of biliary concretions is very various, being sometimes exceedingly small, and at other times of considerable bulk. When small they are generally numerous; I have counted upwards of a hundred, and instances are recorded where more than a thousand were found in the gall-bladder. When they are large they are few in number, and frequently single. I have seen the gall-bladder filled with three, two, and even one large calculus. A large oval gall-stone now before me equal in size to a pigeon's egg I removed from the ductus choledochus. Their *form* is equally various with their size and other physical characters. I have now before me gall-stones with a flattened shape, triangular, and tuberculated on the angles and on the surface; others have three equal facettes with sharp or flattened or rounded angles; others again are irregular in their outline and would seem to be moulded to the canals and cavities from which they have been withdrawn. Being stained by the colouring matter of the bile, their *colour* varies with the predominant tint of the secretion in which they have been formed, hence some are reddish brown or black; others are yellow, and others again white; some are mottled yellow and black, or white and black with various shades of green.

In chemical composition there are, according to Andral, five principal varieties of biliary concretions; they are, 1. of yellow colouring matter; 2. of resin; 3. of cholesterine; 4. of picromel; 5. of phosphate of lime. The first kind appears very ill founded, for yellow is a prevailing tint among gall-stones, and is the mere pigment by which cholesterine and the other substances are coloured. By far the largest proportion of gall-stones are formed of cholesterine, either pure, when it presents a white semitransparent mass beautifully cystallized in its interior, or variously tinted with brown, yellow, or orange, and radiating from the centre towards the circumference or from a small central nucleus. The smaller calculi also exhibit upon fracture the same radiated appearance. The gall-stones of resin and picromel may be classed together and considered as biliary concretions formed of inspissated bile probably accreted through the agency of cholesterine. The calculi of salts of lime are less frequent; they are found in the gall-bladder or in the ductus communis choledochus. I have observed them to present two varieties, firstly, incrustations of phosphate of lime upon the surface of calculi of cholesterine; and secondly, laminated calculi composed of concentric layers of phosphate and carbonate of lime variously coloured and having a central nucleus. The latter form is, I believe, rare; I possess but one specimen; it is of large size, and rough and irregular upon the surface.*

7. *Entozoa.*—The Entozoa met with in the human liver are hydatids or acephalocysts; they are inclosed in a fibrous cyst and are contained in a single parent hydatid vesicle. The internal surface of the vesicle is soft and often pulpy, and covered by minute hydatids which are adherent to its sides. Besides these the parent vesicle is usually filled with a great number of smaller vesicles of variable size. The hydatid cyst generally occupies the right lobe of the liver and increases to a prodigious size, producing absorption of the structure of the organ, and forming adhesions with the neighbouring viscera. The existence of acephalocysts may sometimes be detected during life by the presence of a large tumour in the region of the liver, which forms a projection of the abdominal parietes, is soft and yielding to examination by the hand, and unaccompanied with symptoms denoting cancerous disease. Occasionally the cyst is hardened by deposits of cartilaginous or bony plates. Contracting adhesions with surrounding parts, the hydatid cyst has discharged its contents externally through the abdominal parietes; more frequently, however, it opens into the alimentary canal, as into the stomach or colon. Occasionally it bursts into the cavity of the abdomen, and in one case opened into the lungs, and many of the smaller hydatid sacs were ejected by coughing.

Some small cysts have sometimes been observed in the liver containing a calcareous deposit, mingled with membranous substance resembling fragments of hydatid sacs. These cysts are supposed to result from the spontaneous cure of acephalocysts.

Small intestinal worms have now and then been found in the biliary ducts; these are imagined to have gained admission into those tubes from the duodenum through the ductus communis choledochus.

LUMINOUSNESS, ANIMAL. (*Phosphorescence.*) An evolution of light from the bodies of living animals, independent of the reflection of incident light.

The animals which possess the property of thus emitting light are almost entirely invertebrate, and chiefly marine. We have accounts from several naturalists of certain *fishes* having been seen to give out light while in their native element, and some have conjectured,—but on insufficient grounds,—that all fishes do so. The turtle and a species of toad inhabiting Surinam have been reported to have the same property; and the eyes of some carnivorous mammals appear to emit flashes of light. But we find this function constantly and distinctly manifested only by certain mollusca, insects, crabs, annelida, acalephæ, and zoophytes. These are the following:—

Mollusca
Pholas dactylus
Salpa zonaria
telesii, &c.
Pyrosoma atlanticum
giganteum, &c.

Crustacea
Cyclops brevicornis
Gammarus pulex
Cancer fulgens, &c.
Scyllarus ——— ?

Insecta
Lampyris noctiluca
splendidula
italica
ignita
phosphorea
nitidula
lucida
hemiptera
japonica
Elater noctilucus
ignitus
phosphoreus
lampadion
retrospiciens
lucidulus
lucernula
speculator
janus
pyrophanus
luminosus
lucens
extinctus
cucujus
lucifer
Bupestris ocellata
Chiroscelis bifenestrata
Scarabæus phosphoricus
Pausus sphærocerus
*Fulgora laternaria**
serrata

* Doubts have been expressed by several observers with regard to the luminousness of this insect. In travelling in the countries of South America where it occurs, they have never seen it shine; but the testimony of other naturalists is so decided in favour of it being luminous, that we are constrained to suppose that the animal may give out light in certain seasons of the year and not in others. There can be no doubt, at least, that its congeners above-named are truly luminous.

Fulgora pyrrhorhyncus
candelaria
Pyralis minor
Acheta gryllotalpa?

MYRIAPODA
Scolopendra electrica
phosphorea
morsitans
Julus ——— ?

ANNELIDA
Nereis phosphorans
noctiluca
cirrigera
mucronata
Planaria retusa

ECHINODERMATA
Asterias ——— ?
Ophiura telactes
phosphorea

ACALEPHÆ. Almost all the species of *Medusa, Beroe, Physalia, Rhizophora, Stephanomia, and Physophora*.

ZOOPHYTA
Pennatula phosphorea
grisea
rubra
argentia

INFUSORIA. Many species belonging to the genera *Cercaria, Volvox, Vibrio, Trichoda, Lincophæa*.

With regard to fishes, the statements of naturalists are so contradictory that we still hesitate to admit any of them on the list of truly luminous animals. The sharks, more frequently than other fishes, are reported as luminous. The light given out by them is said to proceed from their abdominal surface. When large shoals of fishes are swimming rapidly, flashes of light, broad and deep, are sometimes seen about them and are supposed to be emitted by the fishes themselves. These appear occasionally at very great depths. They have been traced in the British seas to shoals of herrings and the coal-fish; and Dr. M'Culloch enumerates also the pollack, the pilchard, the sardine, the whiting, the mackarel, and the gar, as being sometimes accompanied by these lights.*

The common earth-worm is not included in the above list, although several observers have reported it as luminous, because the fact of its being so is not sufficiently determined. It is said to give out light only during the period of propagation.

Some voyagers, as Peron, have stated that they have seen *sertulariæ, gorgoniæ, alcyonia*, and sponges give out light immediately after being dredged from the bottom of the sea; but we suspect that in most of these instances the light proceeded not from the zoophytes, but from some light-giving annelids parasitical upon them. This is frequently met with in the British seas.

II. *Characters and properties of animal light.*—It is only in its most obvious qualities that animal light has hitherto been the object of scientific research. In colour and intensity it varies very much at different times in the same animal, and still more in different animals.

* Edin. Encycl. art. *Phosphorescence*.

With regard to *colour* the following varieties occur. In *pholas dactylus* the light is bluish-white; in *lampyris noctiluca* it is greenish with a shade of blue; in *l. italica*, bright blue; in *Elater noctilucus*, brilliant green, with spots of "the most beautiful golden blue;" in *Fulgora pyrrhorynchus*, deep purple and scarlet; in marine animals generally it is white with various shades of blue. Doubtless these differences depend chiefly upon the various colours of the integuments through which the light is seen.

In *lampyris italica*, there are alternate emissions and extinctions of the light, which take place with some degree of regularity and seem to be synchronous with the pulses of the circulating current, visible in the wing-cases of this beetle.*

The fire-fly (*Elater*) shews two kinds of light; one constant, like that of the glow-worm, but more feeble; the other a vivid white light suddenly intermitted. Its illuminating power seems to be greater than that possessed by any other animal; the light emitted from its two thoracic tubercles is so great that the smallest print may be read with it; and in the West Indies, (particularly in St. Domingo, where they are abundant,) the natives use them instead of candles in their houses. They also tie them to their feet and heads in travelling at night to give light to their path through the forest. The intermitting of the light in this insect is such as to give an observer the idea of a membranous veil being suddenly drawn over the source of light, and then as suddenly withdrawn.

In a species of cancer seen by Smith in the Gulf of Guinea, the light (which seemed to be emitted by the brain) was of a deep blue colour when the animal was at rest; but when it moved, bright coruscations of silvery light were darted from it in all directions. The light of some centipedes inhabiting the islands of the Pacific is of a beautiful emerald-green colour. It is connected with a mucous matter covering the animal, which may be rubbed off by the fingers, and communicates to them a smell not unlike that of muriatic acid.

Sometimes the light proceeding from the sea is so white and dull as to give the effect of a sea of milk. This is frequently seen in the Gulf of Guinea, and seems to be caused sometimes by the presence of numerous *Salpæ* and *Scyllari*, at other times by the admixture of the *debris* of fishes and other marine animals recently dead.

An extraordinary series of phenomena connected with a particular display of the luminousness of the sea, is reported by Mr. Henderson as having occurred in the Atlantic, (lat. 2° long. 21° 20′ W.) on the 5th March, 1821. About 9 p.m. the sea appeared unusually luminous. Every person who kept his eye fixed upon it for but a short time was immediately affected with giddiness, headache, pain in the eyeballs, and slight sickness. Although these symptoms varied in intensity amongst the

* A species of *lampyris* lately found in New Holland is said also to shine in rhythmical pulses. Isis, vol. ii. p. 245.

spectators, yet there was not one on board who did not feel some degree of them; and all imputed them to the effect of the light proceeding from the surface of the ocean. Mr. Henderson remarks: "For my own part, the headach, &c. which followed immediately my looking at the water, was particularly severe, nor did it go off until morning. The effects I experienced were like those produced by smoking too much tobacco."*

There have been recorded some accounts of very intense light produced over a great extent of the ocean's surface by luminous animals, but it does not appear that any other voyagers have experienced physical effects from the light such as are described by Mr. Henderson. The great intensity with which it is occasionally produced by marine animals, however, is well illustrated by the descriptions that are given of the moral emotions with which it inspires the beholders. Witness, for instance, Mr. Bonnycastle's description of a scene which he met with in the Gulf of St. Lawrence, (7th Sept. 1826.) While it was very dark, a brilliant light, like that of the Aurora, was seen to shoot suddenly from the sea, in a particular quarter. It spread thence over the whole surface of the water between the two shores of the Gulf; and shortly there was presented "one blazing sheet of *awful* and most brilliant light." "Long tortuous lines of light showed many large fishes darting about as if in consternation at the scene." The light was sufficient to enable one to see the most minute objects on the ship's deck. On drawing up a bucketful of the water, and stirring it with the hand, it presented "one mass of light, not in sparkles as usual, but in actual coruscations."†

Messrs. Quoy and Gaimard state that in handling luminous marine animals while alive, they have always been sensible of an odour proceeding from them similar to that which is perceived around a highly charged electrical apparatus.

The only observation with which we are acquainted that seems to indicate the evolution of heat in connexion with the light of animals, is that reported by Macartney, who states that he found the thermometer raised by two or three degrees when placed in contact with a group of living glow-worms shining, or even with their light-giving sacs cut off. The repetition of this experiment, however, has not produced the same result in the hands of others: they saw no rise of the thermometer.

III. *Circumstances in which light is given out, and by which its intensity is affected.*—It is not known whether there be any luminous animals that give out light in all circumstances, and at every period of their existence, in their natural situations. So far as observation extends, certain *mollusca*, and some of the species of *elater* appear to shine without intermission. But most of the other light-giving animals with which we are acquainted use their peculiar function only occasionally, and that, for the most part, under some kind of excitement or irritation, natural or artificial. In the absence of more direct means of investigation, we may, perhaps, attain to some measure of acquaintance with the nature and analogies of animal light by inquiring into those sources of irritation under which it is given out. Here, however, we are met by the difficulty of finding contradictory statements of facts made by different observers. So that our exact knowledge on the subject is still insufficient to admit of any satisfactory conclusions being drawn. What is known on this point may be conveniently considered under the two following heads.

I. Circumstances essentially connected with the state of nature in which the animals are placed when they give out light.

II. Circumstances artificially produced affecting the emission of light.

I. *Natural circumstances* in which light is emitted by living animals. The luminousness of animals in their natural state is affected by, 1. Changes in the state of the medium in which they live, whether air or water, in regard to its temperature and electricity. 2. By solar light. 3. By abrupt collision with other bodies. 4. By loud noises. 5. By the internal movements of the animals themselves, amongst which may be included the exercise of the animal's will.

1. *Temperature, &c.*—By far the greater number of luminous animals with which we are acquainted are natives of warm climates; but those inhabiting the ocean are seen in almost all latitudes, even in the coldest; although in these they are not so numerous, and give less light. No aërial insects give out light, in ordinary circumstances, excepting at a temperature of about 50° Fahr. and upwards; and the higher the natural temperature, the brighter is the light emitted.

In temperate climates the *Lampyridæ* shine only in summer and autumn. *L. noctiluca* appears in this country between June and September; *L. splendidula*, in Germany, is luminous in May; and *L. hemiptera* so early as in the end of April.

The light of *pholas dactylus* is strongest in summer; and that of marine animals in general is increased before storms.

2. *Solar light.*—It is said that *Scolopendra* does not shine at night excepting it has been exposed during the day to solar light. A short time of exposure to the sun's rays seems to be sufficient to refresh its luminous power, as (like all other light-giving animals) it secretes itself as much as possible during the day. It is stated by Burmeister,* with regard to the *Lampyris Italica*, that if it be kept some days in the dark it entirely loses its luminousness, but regains it on being again placed in the sunshine.

3. *Lunar light.*—Macartney remarked that luminous *medusæ* generally retreat from the surface of the water at moon-rise.

4. *Abrupt collision with other bodies.*—Marine luminous animals very readily emi their light on being struck by any moving body; so that one of the most commonly observed phenomena connected with this subject is the

* Manual of Entomology, transl. by Shuckhard, p. 494.

sparkling of the minute *medusæ* and other animals, swimming on the surface of the sea, when they are dashed against the sides of a ship, struck by an oar, or tossed on the foamy crests of the waves; and this even while no other light is seen excepting just at the points where the water is agitated. In experimenting with *Medusæ*, Macartney found that, when kept in a glass vessel in a state of perfect rest, they gave out no light, but that, on the slightest movement of the vessel, a brilliant flash was emitted, which was brightest when the animals swam near the surface. Macculloch remarks, "Very often we have found the water crowded, even with the largest *medusæ*, yet scarcely betraying themselves by an occasional twinkle, when the dash of an oar or any accidental agitation was sufficient to involve the whole water in a blaze of light."

5. *Loud noises.*—When any loud noise is made near a luminous insect while shining, it frequently ceases to give out its light.

6. *Internal movements of the animals themselves,—will, &c.*—With regard to insects, we have many concurrent testimonies to the fact that more light is emitted during the season of procreation by most of the species than at other times. So strikingly is this the case in the *Lampyrides,* that the light given out by the female has been generally regarded, (although without sufficient reasons,) as destined *only* to attract the attention of her mate. After the eggs are deposited, the light gradually decreases in intensity.

While it is obvious that, for the most part, the emission of light is altogether independent of any voluntary effort on the part of the animal itself, yet it appears probable that, through some means or other, the animal has the power of varying the intensity of the light at pleasure. We cannot, for instance, imagine that sound can have any direct effect on the light-giving organs themselves, so as to cause them to shine less brightly when loud noises are made near them. Such effect must be communicated through the animal's sensorium. It is supposed by some physiologists that variations in the intensity of the light given out by insects depend on the quantities of *air* admitted through the tracheæ in respiration, over which quantities the animal's will seems to exercise some control. In observing the luminousness of the elater, Spix concluded that this control is so perfect, as to admit of the light being wholly extinguished by the animal's preventing the admission of air; and this view is adopted also by Treviranus. These changes, however, are explained by others, (as by Müller and Murray,) by supposing that, when the light seems to fade, the organs are merely withdrawn behind opaque parts, or, as it were, veiled by a curtain.

In general the light is increased when the animal is in motion; and in insects, particularly during flight. Macartney observed of the *beroë*, that when it swam slowly near the surface of the water, its whole body became occasionally illuminated in a slight degree; but that, during its contractions, a stronger light issued from the ribs, and that when a sudden shock was communicated to the water in which it was swimming, a vivid flash was given out.

That the luminous function is in many animals directly under the control of their will, seems to be proved by the fact, that while under any sudden irritation calculated to alarm them, they, at first, emit light strongly, yet on the frequent repetition or continuance of the same kind of irritation, they extinguish their light, and cannot be excited to shew it again for a considerable time.

II. *Artificial circumstances* in which light is emitted by living animals, or by which the emission of it is affected.

Light-giving animals being removed from their natural situations, and subjected to artificial processes and agents, are found to have their luminousness affected by being exposed to, 1. the effects of accumulated electricity and electrical currents; 2. immersion in various fluid and gaseous media; 3. pressure of their bodies; 4. removal of their luminous organs, and mutilation of these and of other organs; 5. exposure to various degrees of heat and moisture; 6. immersion *in vacuo;* 7. removal from all foreign sources of light.

1. The effects of *accumulated electricity and electrical currents.* In experimenting on marine luminous animals, Macartney passed a shock through water in which they were swimming; immediately their light was extinguished for an instant, but afterwards became brighter than before. In reporting the result of a similar experiment, Humboldt merely says that the luminousness of the animals was increased after the shock. Macaire subjected glowworms to the action of galvanism, and found that when one wire was forced through the body of the insect as far as the luminous organs, while the other was applied to the surface slightly moistened, the light became brilliant. One galvanic pole produced no effect; but when insects not shining at the time were placed in a galvanic circle they always began to give out light. This result was not obtained *in vacuo*, but whenever the air was admitted, the light reappeared. No effect whatever seemed to be produced by common electricity, howsoever applied.

2. *Immersion in various fluid and gaseous media.*—Luminous marine animals, when removed from their native element, and plunged into fresh water, give out their light for a time more vividly and more steadily, but afterwards it gradually fades and becomes extinct. Mineral and vegetable acids, alcohol, potassa, and solutions of corrosive sublimate, and the salts, all produce nearly the same effect; only that by these the light-giving property is more speedily destroyed. Observers differ in their accounts of the effects produced by immersion in various gases. Most of those who have experimented in this way have seen the light of the glow-worm very rapidly extinguished in hydrogen gas; also in sulphuretted and carburetted hydrogen, carbonic acid, chlorine and nitrogen gases; but Sir H. Davy found that hydrogen gas produced little or no change in the state of the light; the same was the result of Murray's experiments, who also found

the glow-worm continue to shine in carbonic acid gas. Immersion in oils of all kinds destroys the light-giving property in most of the insects endowed with it; but in *Lampyris italica*, Carradori found that the light continued to be emitted when the luminous part of the body was plunged into oil.

3. *Pressure of their bodies.*—It has been observed that shortly after the death of the insect, the light-giving organs of *elater* emit light freely when the body is bruised, and in general mechanical irritations of all kinds cause a certain degree of increase in the intensity of the light given out. Some animals, as *pennatula*, seem to emit their light rarely, excepting in such circumstances.

4. *Removal of the luminous organs, and mutilation of these and of other organs.*—The luminous organs may be cut out from the bodies of glow-worms and fire-flies without the peculiar property of the organs being immediately destroyed. The emission of light can for some time be re-excited by slight mechanical irritations; as by touching the organs with the point of a pin. Those of the glow-worm have been seen to shine for two or three days after excision, when slightly moistened with water, heated or electrified. In experimenting on the same insect, Todd found that the light was extinguished within six minutes after the head was cut off; as also when the luminous rings were cut into, but was renewable by the application of heat. Sheppard removed the luminous matter from a glow-worm; the wounds healed within two days, and the body became again filled with new light-giving substance.*

5. *Exposure to various degrees of heat and moisture.*—Light-giving insects in general do not shine at any temperature below that of 53° Fahr. Macaire took some glow-worms that had been kept for some time at a temperature of 50° Fahr., plunged them into water at 55°, and gradually raised the temperature. Light was emitted for the first time at 77°, and increased in intensity until the water was at 105°. At this temperature the animals died, but the light continued until the temperature had reached 134° 5, when it wholly disappeared. When glow-worms are thrown alive into water heated to 110° and upwards, they die instantly, but at the moment emit a brilliant light. When they are exposed to an artificial cold suddenly, they perish at any degree below the freezing point of water; but the light may be partially restored by a temperature of 70°, although the animals shew no other sign of vitality. When the insects are dried artificially, the light is extinguished, but it may be restored by their being again moistened.

6. *Immersion in vacuo.*—When glow-worms are placed *in vacuo*, their light fades, but reappears on admission of air.

7. *Removal from all foreign sources of light.*—If luminous insects be confined in a dark place, they shine little in the early part of the day, but long before night they begin to do so; although generally, in their native situations, they do not emit light until the twilight. If the confinement in a dark place be protracted, they do not shine so brightly as after having seen the sun during the day.

* Kirby and Spence's Entomology, ii. 426.

IV. *Seat of luminousness in different animals.*—In most of the luminous animals that inhabit the ocean, a great part of their surface seems to be endowed with the property of forming, and pouring out, a mucous fluid, which contains the luminous matter, and is frequently miscible with water and other fluids. This sometimes so entirely covers the whole animal as to cause it to emit light from every point of its surface; but more generally when the animal is swimming, the light is seen to proceed only from certain regions. Some of the *medusæ*, even of the largest size, emit light from a very small point, particularly when the luminous organ is placed in the central parts of the body. When the light is vivid, it seems to be larger than it really is, from the refracting power of the gelatinous tissues through which it passes. Occasionally the luminous point has not a diameter equal to the 1-200th of that of the animal itself. In *cydippe pileus* and *oceania pileata* of the Baltic, Ehrenberg finds that the light issues solely from the vicinity of the ovaries, and in *oceania hemispherica*, from the bases of the cirri. *Pholas dactylus* gives out light most strongly from the internal surface of its respiratory tubes. The luminous mucus is sometimes poured out even by very small animals in such quantity as to leave a luminous wake behind them, as in an instance mentioned by Quoy and Gaimard. These observers saw such luminous lines formed in the paths of certain extremely small creatures, so transparent that their forms could not be distinctly made out. The positions of their bodies were marked in the water by bright spots, which were followed in their course by luminous wakes, at first about an inch in breadth, but afterwards by the movements of the water spread out to the breadth of two or three inches. This luminous mucus is supposed to be the seat also of the remarkable stinging property possessed by many of the *acalephæ*. It retains its luminousness in some instances for a day or two after being emitted by the animal, but loses it whenever putrefaction commences.

But although this luminous mucus be so generally secreted and emitted by marine animals, it is evident that the light given out by many of them has its seat in certain organs more or less internal, whence it proceeds in gleams and momentary flashes that seem to depend only on the movements of some imponderable agent. The exact position and relations of these organs can seldom be satisfactorily discovered, but in some crabs and minute crustaceous animals that emit light, it is observed to proceed from the central organs of the nervous system. In other crustacea the whole body seems to be full of light, which is emitted, as at so many windows, through the translucent membranes interposed between the segments of the crust. Dr. Macculloch concludes from his numerous observations on this subject, that, in marine animals generally, the coats of the stomach and intestines are the light-giving organs.

In insects the seat of luminousness is more satisfactorily ascertained, and is found to vary very much in different species and tribes. The eggs of the *lampyrides* are said to be frequently seen luminous, and to continue so for several days after being deposited. In the states of larva and chrysalis also, the same insects emit light most vividly when touched, chiefly from the posterior segments of the body. On being much irritated, the whole of the chrysalis seems to shine in a slight degree, and for a short time.

In the perfect female glow-worm of this country, the light is emitted chiefly from the inferior and lateral surfaces of the two or three last segments of the abdomen. The male of the same species presents only two small luminous points on the sides of one of the segments. When the light-giving surfaces of the female *lampyris noctiluca* are narrowly examined, it may be seen that, on the penultimate and antepenultimate segments, they present bands of a bright greenish-yellow light, which are abruptly terminated towards the trunk by an irregularly waved line; and that from the rest of the same segments there issues a fainter light of a pale green colour. There is also a little light given out by the posterior extremity of the dorsal line. In *L. italica*, the two last segments are wholly and nearly equally luminous. Most of the glow-worms in displaying their light recurve their tails upon their backs, so as to bring their luminous surfaces into view.

Elater noctilucus gives out light principally from two points of the thorax, which are somewhat raised, and of an oval shape; but it has also two light-giving organs situated beneath the wing-cases, which are not seen except when the insect is flying. Light is also emitted from the internal parts through the interstices between the abdominal segments.

In *bupestris ocellata*, the light is emitted from certain yellow spots upon the *elytra*: in *scarabæus phosphoricus* from the belly: in *chiroscelis bifenestrata*, (a New Holland insect) from two oval, hairy, reddish spots on its second ventral segment; while, in *pausus sphærococcus*, a dim phosphoric light issues from its singular hollow globular antennæ.

Macartney says that he always observed the shining of *scolopendra electrica* to be accompanied by the appearance of an effusion of a luminous fluid upon the surface of the animal, paticularly about the head. On touching this, his finger and other bodies received on their surface a phosphoric light, which continued to shine for a few seconds, and then died away; and yet he could not see any actual moisture, even upon smooth glass, although examined immediately and attentively.

The researches of Treviranus have led him to conclude that there is no special luminous organ in insects; but that the generally diffused fatty matter is the seat of the function, by which the luminousness is produced. He concludes, therefore, that, when the air has free access to the interior of the body through the respiratory tubes, the whole of the internal organs give out light; and that this is not seen, excepting at certain points of the surface, merely because the integuments are not translucent.

V. *Anatomy of light-giving organs.*—The accounts of examinations of these organs that have hitherto been published are rather imperfect. This appears to be owing chiefly to the fact that the organs themselves are of very simple structure and furnish no materials for lengthened description. So much so are they in insects, that one would be inclined readily to conclude with Treviranus, that they are nothing but the common fatty or interstitial substance which fills up the bodies of insects, slightly modified by the presence of some phosphoric matter, were it not for the fact, particularly observed by Macartney, that, in the glow-worm, the luciferous organs are absorbed after the season for their use is past, and their places supplied by the fatty substance. The following are the results obtained by this naturalist and by Spix from their dissections of the glow-worm, the fire-fly, and the lantern-fly.

In the glow-worm, there is spread over the internal surface of the segments of the abdomen a yellowish substance of the consistence of paste, which is thickest in the middle of each segment, and terminates near each margin by a wavy outline. It is of a closer texture than the fatty matter, but otherwise resembles it. Besides this substance, the last segment is furnished internally, just beneath the most transparent part of its integument, with two small round bodies, lodged in depressions, which contain yellow matter of more close and homogeneous texture. Müller and Murray describe these round bodies as "two small ovate sacs, composed of thready membranes, and filled with a soft yellow pasty matter." Under the microscope, they appeared to Macaire to be composed of numerous branching filaments, with minute granules adhering to them. It is from points of the surface corresponding to the situation of these round bodies that the light is most constantly and most brightly emitted. When dry, these luminous organs have somewhat of the appearance of gum. The dried matter is translucent and yellowish, becomes darker on being kept, and appears to be granular in its structure. Its specific gravity is a little greater than that of water.

In the fire-fly, the internal concavities of the yellow spots of the corselet, whence the light proceeds, are filled with a soft yellow substance, oval in shape, and of very uniform consistence and density. This, under the microscope, appears to be formed of a large number of very minute parts or lobules, closely pressed together. Around these oval bodies, the fatty matter of the corselet is arranged in a radiated manner. Spix describes the same organs as "yellowish glandular masses, into which many branches of the trachea enter."

In *elater ignitus* the masses of luminous substance are extremely irregular in their figure; they are situated close to the posterior angles of the corselet, and are more loose in their structure than the same parts in *elator noctilucus*.

The luminous proboscis or snout of the *fulgora* is hollow, and has a free communication with the external air by a narrow slit situated near the base of the organ. Its cavity is lined with a fine membrane, between which and the outer translucent corneous crust, there is interposed a soft tissue of a pale reddish colour, arranged in lines longitudinally, which is supposed to be the seat of luminousness in this insect.

In several instances it has been found that the light-giving substance has continued to shine for a considerable time after being removed from the body of the insect. In such cases it has been observed that there appeared to be no diminution either in the weight or the bulk of the luminous organs, excepting what was obviously produced by evaporation of the fluids.

VI. *Geographical distribution of luminous animals.*—In almost all seas, in every latitude from 60° S. to 80° N., have light-giving animals been seen; but they are more abundant, and shine with greater brilliancy, in the tropical than in the colder climates. In general, it is observed by voyagers, the luminous mollusca and acalephæ occur in greatest numbers not far from land; and that they are particularly plentiful in the seas surrounding groups of small islands within the tropics.

The luminous insects are met with chiefly in the warmer climates of the temperate zones and within the tropics. We are not aware of any having been met with beyond the latitude of 58°.

VII. *Theories of animal luminousness.*—Very numerous have been the theories formed by philosophers with regard to the nature of the luminous matter which produces the phenomena now under review. From the facts stated above, it appears that we are not yet in a position to determine with certainty whether or not animal luminousness has its source in the operations of any agent already known. At least it appears to us that facts enough have been accumulated to set aside the assumption of most of the theories hitherto promulgated. The following are some of these.

1. That light is imbibed from the sun's rays by luminous animals and given out in the dark. (Beccaria, Mayer, &c.)

2. That the light is owing to a kind of combustion maintained by the oxygen of the air. (Spallanzani.)

3. That light is swallowed with the food, and disengaged by peculiar organs. (Brugnatelli.)

4. That the light-giving matter is composed of phosphorus and albumen; and that the variations in the intensity of the light depend on the more or less complete coagulation of the albumen, by some internal means placed under the control of the animal's will. (Macaire.)

5. That a fluid containing phosphorus is secreted by the luminous organs, and shines on its being exposed to the oxygen of the air introduced by respiration. (Darwin, H. Davy, Heinrich, Treviranus, and Burmeister.)

6. That the luminous organs concentrate and modify the nervous influence so as to form it into light; so that, according to this theory, animal luminousness is an effect *solely* of *vital* power. (Macartney and Todd.)

7. Tiedemann thus expresses his opinion: "Animal luminousness would seem to depend on a matter, the product of the changes of composition accompanying life, and, to all appearance, secreted from the mass of humours by particular organs. This liquid probably contains phosphorus or an analogous combustible substance, which combines with the oxygen of the air or of aërated water at a medium temperature, and thus produces the disengagement of light. The preparation and secretion of this substance are acts of life, which change, augment, or decrease by the influence of external stimulants, whose action on the animals modifies their manifestations of life. But the phosphorescence itself depends on the composition of the secreted matter and cannot be regarded as a vital act; because, on certain occasions, it continues for whole days and even after the death of the animal." *

This opinion seems to coincide pretty nearly with that of Darwin, Heinrich, and others, stated above (5); and we must admit that it appears to harmonize the facts better than any of the other theories that have been propounded. But, while it seems satisfactorily to assimilate many of the phenomena to others more familiar to us, and more within the reach of our investigations, and thus appears to furnish future inquirers with a key to the elucidation of what yet remains obscure, it is obvious that it leaves some of the phenomena unexplained, and that several of these seem to be quite irreconcilable with the theory of the phosphorescence being essentially dependent on the composition of secreted fluids. In some of the extremely delicate *acalephæ*, for instance, from which the brightest radiance is so frequently emitted in momentary fitful flashes, it is difficult to conceive why, if the light mainly depended on the nature of some matter poured out by certain organs at the instant of the flash, the light should not continue for at least a few seconds. The circumstance of its doing so in some instances, and even mixing gradually with the surrounding sea-water, certainly proves that there is such a fluid as this theory supposes in certain animals; but does not remove the difficulty presented by the facts we have alluded to.

We feel ourselves constrained by these and other such facts to believe (with Macartney and Todd) that in many, perhaps in all, luminous animals, both terrestrial and marine, the light emitted is the consequence of an evolu-

* Comparative Physiology, translated by Drs. Gully and Lane, i. 270.

tion of an imponderable agent by the nervous systems of the animals, just as the electrical fishes give their shock without the interposition of any visible or ponderable secretion. In this view we may regard the luminous organs as playing the same part in relation to the evolution of light as the electrical organs of the torpedo do to the production of the shock. The single fact of luminousness continuing in the organs or in their effused fluids, after they have been removed from the body of the animal, seems to point to a great difference existing between the two classes of phenomena which we have just compared, in certain animals; but it may be that the difference is more apparent than real; for this fact may be explained by supposing that a phosphoric substance really does enter into the composition of the light-giving organs; and yet we may with great probability conjecture that *it* is not the *chief* agent in causing the phenomena of luminousness. It remains, then, for future inquirers to determine the chemical composition of the luminous organs, and the fluids emitted by the animals, the phenomena of whose luminousness seem to be irreconcileable with the idea of their being dependent on the nature of these fluids; if they be found to contain phosphoric matter, it may be concluded that, as this does not appear to be essential in them to the production of the phenomena of luminousness, so neither may it be in other animals, in which it is believed to be the chief agent in the manifestation of their light-giving function.

To this theory, (which is only a combination of the two most generally received in modern times,) we do not, in the facts which have come under our notice, see any serious objection. The only argument adduced against Macartney's theory by Tiedemann and other physiologists, who have carefully considered the facts of the case, is founded on the circumstance of the light continuing, in a certain degree, for some time after the death of the animals, which, of course, cannot be supposed to be owing to the continued operations of the nervous system. This posthumous light, however, may depend on the phosphorescence of the luminous organs or their effused fluids in virtue of their composition, while the full evolution of light during life may be produced chiefly by the play of imponderable agents in and from the nervous system, independently, in some cases, of the chemistry of the fluids; in other cases, aided and modified by the nature of these and by the structure of peculiar organs.

It is scarcely necessary to take particular notice of the various other theories that have been suggested, as the facts stated in the preceding part of the article are sufficient to set them aside.

VIII. *Uses of animal luminousness.*—We know nothing certainly with regard to the uses of the light-giving function; but as almost all observers have remarked that male insects seem to be attracted towards their mates by the brilliancy of the light emitted by the latter, it has been generally supposed that the luminousness is subservient to the generative function. Although it may be so to a certain extent, it is obviously not essentially connected with it, even in the glow-worm; for the light endures long after the season of love is past. Some have conjectured that the light may sometimes be the means of preserving its possessors from the destructive attacks of enemies. Thus Sheppard observed a large beetle running round a shining *scolopendra*, as if wishing to attack it, but seeming to be scared by the light. We may imagine, also, that the light enables its possessors to see surrounding objects at night, and so to thread their way in safety through the darkest places.

Considering that, in the ocean, there is absolute darkness at the depth of 800 or 1000 feet, at least that, at such depths, the light of the sun ceases to be transmitted, Macculloch has suggested* that, in marine animals, their luminousness may be "a substitute for the light of the sun," and may be the means of enabling them to discover one another, as well as their prey. He remarks, "It seems to be particularly brilliant in those inferior animals which, from their astonishing powers of reproduction, and from a state of feeling apparently little superior to that of vegetables, appear to have been in a great measure created for the supply and food of the more perfect kinds."

IX. *Luminousness of animals not innate, and other allied phenomena.*—We have accounts of the surface of the human body appearing luminous in consequence of phosphoric matter being largely mixed with the sweat in the course of various diseases. The urine also both of men and several of the lower animals is occasionally luminous under similar circumstances. It is said that the urine of *Viverra mephitis* and *V. putorius* is always so.†

The eyes of human albinoes, almost all the mammalia which possess a *tapetum lucidum*, as also those of some birds of prey, serpents, and insects, seem to shine in a feeble light from the reflexion and concentration of the rays falling upon them from external objects. Pallas thought that this light was developed in the *retina*, and regarded it as an electrical phenomenon. But it has been plainly proved by Prevost, Gruithuisen, and Esser,‡ that the shining of the eye depends, in most cases, on reflexion of light. They found that there was no appearance of luminousness in absolute darkness; and that the eyes of dead animals gave the same effect as those of the living, when placed in similar circumstances.§

It would appear, however, from some observations made by Rengger on the eyes of a certain South American ape, (*Nyctipithecus trivirgatus*,) that there is reason to believe in

§ See also Hessenstein, de Luce ex quorundam animal. oculis prodeunte, atque de Tapeto lucido. Jenæ, 1836.

the emission of light from the eyes of some animals, independently of the reflexion of incident light. The ape in question is nocturnal. The luminousness of the eye was seen by Rengger only when there was total darkness; and then the light was so brilliant that objects at the distance of a foot and a half from the eye were distinctly seen.* In commenting on this statement by Rengger, Treviranus remarks,† "that the intensity of light may be increased by the brilliant *tapetum* of the eye, while it is concentrated as in a concave mirror, cannot be doubted. But it is impossible that a feeble light so concentrated should illuminate objects placed at the distance of a foot and a half from the eye of this ape, in a dark place." The same physiologist seems to be satisfied that some dogs also have a similar power of generating light within their eyes. In these, he states, the light is seen only when an impression on the sight or hearing arouses the animal's attention, or when he is excited by the operation of some instinct or passion.

We are, therefore, constrained to conclude that this subject is still open for elucidation by future inquirers. If it should be proved that some of the higher animals really do emit light from their eyes, independently of the incidence and reflexion of that from without, it will go far to render it probable that, in luminous animals generally, the development of light depends more upon the movements of some imponderable agent in and from their nervous system, than upon the nature of the composition of the fluids poured out by the luminous organs.

Another series of phenomena, intimately connected with, and illustrative of, those previously considered, demands notice here, namely, the shining of fishes, and other animal bodies shortly after death. The luminousness of dead fishes is a very common subject of observation, but not on that account the less worthy of particular attention. It has been ascertained that the light is given out from every part of the body, external and internal, that is exposed to the air; and that on the surface of the luminous parts there is a slight moisture, or solution of the tissues of the animal, which can be scraped off, or diffused in water, and continues luminous for a short time after being so removed. When pieces of the skin or muscle of a fish are placed in a little water, the luminousness appears only on the surface when the water is at rest; but whenever it is agitated the light is diffused through the whole body of water.

In some fishes, as the whiting, this luminousness appears within a very short time after death; in others, not for some days; but in all it ceases before the truly putrefactive process has commenced. It is observed that those fishes which most quickly putrefy, are also those which give out light the soonest.

From the circumstance mentioned above, that this luminous fluid formed on the bodies of dead fishes is miscible with water, and retains its luminousness for a short time after being so mixed, it has been concluded that the beautiful phenomenon of the phosphorescence of the sea may be frequently owing to the presence, in great quantity, of the remains of fishes recently dead. It is certain that the most careful observers sometimes fail to detect any entire living animals in sea water taken up from a brilliantly luminous sea; and find only abundance of small fibres and shreds of what seem to be broken-down animal tissues. Professor Smith* concluded from his own observations made in the Atlantic, that, while the bright sparkling light of the surface of the ocean is always emitted by living animals, that duller diffused luminousness, which is frequently seen over a vast extent of the sea, giving it the appearance of milk, is given out by "a dissolved slimy matter, which spreads its light like that proceeding from phosphorus." Under the most powerful microscope, Smith saw nothing in such water but "the most minute glittering particles, having the appearance of solid spherules." Humboldt saw a great extent of the surface of the sea rendered almost gelatinous by the admixture of numbers of dead *dagysæ* and *medusæ*.

It may, therefore, be regarded as probable, at least, that the luminousness of the ocean is *sometimes* caused by dead matter; but it is certain that, in the great majority of instances, it is entirely owing to the presence of living animals, possessed of the light-giving property.† In attempting to examine these, so as to determine their forms and habits, it is important to keep in mind that they are sometimes extremely small, so as to be distinguished with considerable difficulty, even with the aid of the best microscopes. And when they are larger, they are frequently so transparent as to elude notice.

LYMPHATIC AND LACTEAL SYSTEM.

—(Fr. *Système lymphatique;* Germ. *Saugadersystem oder Lymphgefässsystem.*

* Tuckey's Voyage, 258.
† Martin, Canton, Hulme, and others supposed the luminousness of the sea to be caused by a phosphorescent oil, generated during the putrefaction of animals. Silberschlag regarded it as phosphoric. Mayer, Beccaria, Monti, Brugnatelli, and others, believed it to be owing to the giving out of light imbibed from the sun's rays. Bajon, Delaperriere, and Gentil imputed it to electrical agency, because it is excited by friction. Foster supposed it to be sometimes electric, and sometimes putrefactive.

Syn. *Absorbent system.)*—The lymphatic system is composed, in the first place, of the vessels which collect and convey the lymph from all parts of the body and the chyle from the intestines, and ultimately deposit them in the veins. Secondly, of the small fleshy bodies called conglobate, lymphatic, or absorbent glands, which are found connected with this system of vessels in various parts of their course.

The lymphatic system is confined to the class Vertebrata. It is the least complicated in Fishes, and consists in them simply of pellucid valveless vessels. In Reptiles, also, it is composed of these vessels only, but which are armed with more or less perfect valves. In the two higher orders of Vertebrata, Birds and Mammalia, to the vessels containing very numerous and perfect valves, the conglobate glands are superadded: in all, however, the termination of the system is in the veins, and its origin and general arrangements are probably in all essentially the same.

The different parts of the lymphatic system had escaped the notice of anatomists until the middle of the sixteenth century, and the entire system was not discovered till the middle of the seventeenth. I must here except the lymphatic glands, which from their large size must have been observed by the earliest anatomists, and we accordingly find them alluded to by Hippocrates, who classed them with the other glandular organs.

The first isolated discovery in the vascular part of this system was made by Eustachius in 1563, who saw and described accurately the thoracic duct in a horse. He called it the *vena alba thoracis*, and traced it downwards from the left subclavian vein to the lumbar vertebræ, where he noticed the dilatation now called the receptaculum chyli; he however had no conception that it formed the trunk of a separate system of vessels, but conceived it to be a vein of a peculiar kind. Fifty-nine years afterwards, in the year 1622, Asellius was fortunate enough to discover the lacteal vessels on the mesentery of a dog; and although on the following day he was much disappointed in not being able to see them in another dog inspected for the purpose, by continuing his researches he soon convinced himself of their existence in most animals. He also attributed to them their proper function, having remarked that whenever there was chyle in the intestines, these vessels also contained a white fluid, and could then only be seen. He failed, however, to connect the vena alba thoracis, the discovery of Eustachius, which had probably been forgotten, with his own, and mistaking the lymphatics of the under surface of the liver for the continuation of his vessels, was led into the error of supposing them to terminate in the liver. Asellius, who died in 1626, had not seen the lacteals in man, but inferred and asserted their existence. According to Haller, Veslingius was the first who saw these vessels in the human subject, in the year 1634; but Breschet informs us, in his Systême Lymphatique, page 4, that, "en 1628, les lymphatiques du mésentère furent aperçus pour la première fois chez l'homme. Peiresc, Senateur d'Aix, informé par Gassendi de la découverte qu'avait faite Aselli, distribua plusieurs exemplaires de l'ouvrage de ce proffesseur aux medecins de sa connoissance, et leur abandonna un criminel condamné à mort, pour verifier le fait sur son cadavre. On fit bien manger cet homme avant de le conduire au supplice, et une heure et demie après sa mort, l'ouverture du bas ventre montra le mésentère tout couvert de vaisseaux lactés pleins de chyle."

The thoracic duct was rediscovered in the year 1649, by Pecquet, who published a description of it in 1651. Haller ascribes this discovery to Veslingius: "Idem Veslingius, nisi plurimum fallor, primus post Eustachium, contra omnes coætaneos, rectius anno 1649, vidit vas lacteum grande, in pectus adscendere; cum reliqui incisores, partim ab Asellio persuasi, et partim a lymphaticis vasis hepatis seducti, chyliferos ductus ad hepar ducerent."

It now became evident that the thoracic duct was the trunk of the vasa lactea, and that the chyle was not conveyed to the liver, as Asellius supposed, but was poured into the venous system at the union of the subclavian and internal jugular veins of the left side. The lymphatics of the under surface of the liver were soon after shewn by Glisson and Veslingius to have their valves so arranged as to convey their contents from, and not to this organ.

In the two or three following years the rest of the lymphatic system was discovered by Rudbeck in Sweden, by Bartholin in Denmark, and by Jolyffe in this country; nor was it long before the function of absorption was ascribed to it by Glisson, in 1654, and by Hoffmann. Since this period, we have been indebted for various details of the arrangement of this system of vessels in man and other Mammalia, in Birds, in Reptiles, and Fishes, to numerous investigators, Nuck, Ruysch, Albinus, Meckel, Hunter, Monro, Hewson, Cruickshank, Sœmmerring, Mascagni; and in the present day to Fohmann, Lauth, Lippi, Rossi, Panizza, and other continental anatomists.

The lymphatic vessels in the human subject are exceedingly delicate and transparent tubes, numerous but small, existing in most if not in every part of the organism, crowded with valves, and terminating, after passing through the glandular bodies, in two principal trunks, through which the contents of the whole system are emptied into the circulating venous blood at two corresponding points not far distant from the heart, viz. at or close to the angles of union between the subclavian and internal jugular veins. The two trunks of the lymphatic system are by no means symmetrical. That which enters the veins on the left side measures as much as sixteen or eighteen inches in length in the adult human subject. It commences in the abdominal cavity by a slightly marked dilatation, the *receptaculum chyli*, into which the chyliferous vessels pour their contents; it then passes through the thorax to reach its termination in the neck. This trunk is usually termed the *thoracic duct;* it may be said to receive the lymph of three-fourths of the body, together with the whole of the chyle. The right lymphatic trunk is about two lines in diameter, very short, corresponding in situation and length to the last half-inch of the left trunk; consequently it will only be found at the root of the neck, close to the point of its termination. This trunk receives the remaining fourth of the lymph, viz. that collected from the right upper fourth of the body. Professor Lippi published a work on the lymphatic system in the year 1825, in which he described in the human subject many terminations of the lymphatics in other parts of the venous system, especially in the vena cava inferior, the vena portæ, and the principal branches by which these vessels are formed, but subsequent observers have not corroborated his views. The vessels which Professor Lippi saw joining other large venous trunks were evidently the returning veins of the conglobate glands, into which the injection received by the lymphatics had passed during its transit through the glands:—a fact of extreme interest, and to which we must recur in speaking of the structure of the glands, but which has been observed by every anatomist who has had much practical experience in injecting the lymphatic system. Lippi would have been perfectly correct, however, had he confined his statement to what takes place in Birds, Reptiles, and Fishes.

The lymphatic vessels resemble the veins in possessing valves, and in conveying their contents from branch to trunk; moreover their internal tunics are continuous where the one set of vessels joins the other. In their mode of distribution also throughout the body the analogy between the two systems is considerable. Eustachius, when he first saw the principal trunk of the lymphatics, from its being filled with chyle, at once described it under the name of the vena alba thoracis, and many have considered the lymphatic vessels as an appendage to the venous system, rendering it more perfect. Although we are warranted in saying that the lymphatic vessels convey their contents from branch to trunk, by which is generally understood from smaller and more numerous to larger and less numerous vessels, as is the case with the veins; yet is there another principle apparently of an opposite kind observed in their distribution, by which the influence of capillary attraction is engaged in the important service of moving onward their contents, at the same time that these are exposed to a larger surface of the containing vessels, from which in all probability they derive some essential modification. This admirable and simple provision is especially evident in the lower extremities, where the greatest resistance from gravity is to be overcome. A vessel on the instep, for instance, of half a line in diameter, instead of emptying itself into a larger one as it proceeds upwards, bifurcates into vessels of equal diameter with itself; each of these again will in a similar manner subdivide, until at length by a series of dichotomous divisions, although some reunions may take place, this single vessel has multiplied itself by the time it reaches the inguinal region into as many as fifteen or more branches, each of the same diameter or nearly so as the original branch on the instep. Indeed, throughout the lymphatic system, we scarcely find a branch of more than an inch in length whose diameter is not within the range requisite for the production of capillary attraction. The thoracic duct itself, which is two or three lines in diameter, may be said to form an exception, but the onward progress of its contents is specially provided for by its juxta-position to the aorta, from which circumstance it is subjected during life to an alternating pressure of considerable force, and fully competent in a vessel provided with valves to ensure the advance of its contents.

The principal lymphatics in any part of the body may be said, taken collectively, to equal the capacity of the arteries or veins of the same part; thus, in the inguinal region the sum of the diameters of the lymphatic vessels may equal the diameter of the main channel by which the venous blood is returned from the lower extremity; but by this simple subdivision of the outlet for the lymph into numerous branches, that almost universal, and, in its effects, wonderful power, by which the nutrient fluid throughout the vegetable creation is carried from the lowest fibril of the root to the highest living point in vegetable existence, is made available in the progression of the lymph in animals towards the centres of the system. This disposition of the lymphatic vessels throughout their course necessitates a greater uniformity in point of size, than we find to hold good with the artery or vein, and indeed constitutes their chief peculiarity in distribution when compared with the other divisions of the vascular system. The arborescent appearance, except on the surface of the liver and spleen, is scarcely to be met with in the lymphatics; they almost always form a net-work of vessels, the meshes of which vary both in form and size in the different organs and in different parts of the body; as a general rule, when the vessels have a short course to run, the spaces they enclose are small and more nearly equilateral; but when the contrary is the case, as occurs in the extremities, the meshes are very large and much elongated, so that the vessels run nearly parallel with each other, and the net-work arrangement is scarcely perceptible; there is, however, still less appearance of arborescence.

In this respect the lymphatics may be said to resemble more the capillary bloodvessels, which in the web of the frog's foot, or in the vesicular lungs of the salamander, toad, or frog, are so plainly seen to form a net-work of nearly equal-sized vessels, and, indeed, to cease to be capillaries when they become arborescent.

Another peculiarity in the disposition of the lymphatic vessels occurs at their approach to a conglobate gland, through which their contents are to be conveyed. The vessels leading to a gland which are termed the *vasa inferentia* or *afferentia* of the gland, vary in number, being seldom less than two, and rarely amounting to more than five or six. They maintain their ordinary size and appearance to within a quarter of an inch of the gland, where they suddenly branch out, artery-like, into several exceedingly minute vessels which plunge into the gland, thus conveying the lymph, in a minutely divided state through this organ to emerge again from it by a converse arrangement of equally small vessels, which at a quarter of an inch from the gland, are collected like so many small veins into one or more trunks, called the *vasa efferentia* of the gland; not unfrequently there is but one of these vessels passing from a gland, and rarely more than two or three; they are, however, generally larger than the vasa inferentia, and often double their size. (*Fig.* 52.) A similar arrangement in the bloodvessels before entering or passing from their appropriate glandular organs may be noticed in the spleen and kidney, but the only instance in which a bloodvessel collecting its contents from branches assumes the opposite function of distributing them into narrow streams occurs in the vena porta, where the blood is to be passed through the liver to be subjected to its action. The same object, it is true, is effected at the heart with the blood of the venæ cavæ, together with the lymph and chyle, when conveyed in capillary streams through the lungs to be converted into arterial blood; the right side of the heart, however, here intervenes between the collecting vessels and those which have to redistribute the blood; the latter also are called arteries though they convey the same venous blood to the lungs which the former vessels brought to the heart.

The vasa inferentia are by most authors described as entering that edge of the gland which is farthest removed from the trunks of the system, and the vasa efferentia that nearest to them. This I find not to be the case; the vessels usually plunge into and emerge from the broadest surfaces of the gland; sometimes it is the deeper surface, sometimes the more superficial, and frequently both. The vasa inferentia may enter one surface, and the vasa efferentia pass from the same or the opposite surface of the gland. The vasa efferentia, as they proceed onward, become the vasa inferentia of succeeding glands; thus the lymph is often made to traverse several glands before it is received by the trunks of the system. This is so much the case in the neighbourhood of the thoracic duct, especially in the pelvic and abdominal cavities, that the lymphatic system assumes altogether a different aspect; the network appearance, the uniformity in point of size, are lost sight of in the numerous large short vasa efferentia and inferentia, intervening between the closely set glands. The appropriate lymphatic vessels of the viscera and walls of these cavities, nevertheless maintain the ordinary disposition, the apparent irregularity depending upon the circumstance, that the large lymphatics of the lower extremities, are interrupted by numerous glands in their passage to the thoracic duct.

The lymphatic vessels are distributed throughout the body on two planes, one superficial, the other deeply seated. The vessels of the two planes where they approach each other communicate freely. A similar arrangement takes place partially in the venous system; and it is interesting to remark that where this occurs, the veins, like the lymphatics, are armed with valves. We cannot fail to recognize here a double provision to facilitate the progress of the contents of a vessel towards their proper destination; while the valves prevent effectually any retrograde movement, the double plane of vessels, by increasing the number of channels, lessens the liability to arrest from the various causes of obstruction. The superficial lymphatics accompany more or less the superficial veins where these occur, but in other parts of the body they assume various appearances peculiar to each viscus or organ; the superficial lymphatics, of the liver, spleen, kidney, and lungs, for instance, differ materially from each other in arrangement and appearance. The deep-seated lymphatics every where follow the course of the large bloodvessels. They are fewer in number and perhaps rather larger than the superficial. The superficial and deep lymphatics communicate with each other in the lymphatic glands as well as in different parts of their course.

The chief peculiarity of the coats of the lymphatic vessels is their remarkable thinness and transparency; in other respects they bear considerable resemblance to the coats of the veins; indeed in some of the lower animals the veins are nearly as thin, and when empty of blood, as transparent as the lymphatics. All anatomists admit the existence of two coats in the lymphatics, an internal serous lining, which at intervals is thrown into folds to form the valves, and an external thicker fibrous covering; to these is added by some anatomists, with whom I am disposed to coincide, a third, analogous to the cellular tunic of the bloodvessels, which conveys to them their vasa vasorum, and by which they are connected to the surrounding structures.

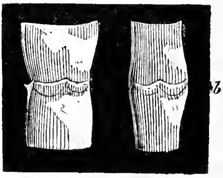
The inner tunic is extremely fine and delicate, probably less elastic and extensible than is generally imagined, and is the first to give way under distention from forced injections. It appears to possess a much closer texture than the fibrous tunic, to which it is firmly adherent, and whose contractions and dilatations it is compelled to follow. The epithelium scales are distinguished with difficulty on the inner surface of this tunic, but I have satisfied myself of their existence. On placing an opened lymphatic in the field of the microscope after the bloodvessels have been minutely injected, the vasa vasorum may be very distinctly seen; but it is difficult, from the perfect transparency of this tunic, to say whether these vessels reach it, or are only seen through it. The vasa vasorum of the lymphatics do not appear to affect any constant or fixed arrangement; they are by no means numerous, and I have never been able to detect any on the valvular folds.

The fibrous tunic, like the internal, is transparent; it is very elastic, and admits of considerable distention without rupture. There is great variety of opinion with respect to the nature of its tissue. Breschet and many other anatomists describe this tunic as resembling the cellular coat of the bloodvessels, and are under the impression that the lymphatics are altogether deficient in that which is analogous to the middle or fibrous coat of the arteries and veins. Mascagni and Rudophi have not been able to detect muscular fibres in it. Cruveilhier conceives it to be composed of the tissu jaune elastique, or tissu dartoide. Schreger thinks he has seen circular muscular fibres in the thoracic duct of man and of large animals, and Sheldon states that he has distinctly seen muscular fibres in the thoracic duct of the horse. By placing a portion of the thoracic duct or large lymphatic laid open with the lining membrane uppermost, on a piece of glass, and by scraping off the internal membrane, the fibrous tunic will be exposed; if it be now moistened with a drop of water, and a piece of talc placed over it, it may be readily examined under the microscope. I have several times examined portions of the thoracic duct and of the larger lymphatics taken from the horse, and from the human subject, and have invariably found the tunic exposed on removing the lining membrane, to be composed of fibres passing principally in the longitudinal direction; these fibres are uniform and cylindrical, and resemble in these respects the organic muscular fibre as described by Schwann; they lie for the most part parallel with each other, and are occasionally seen to form a large fasciculus, somewhat analogous to the longitudinal muscular bands of the large intestine. These fibres measure from 1-5000th to 1-6000th of an inch in diameter, and present at intervals, a sudden zigzag inflection; several fibres collected together into a sort of primitive fasciculus are bent together at the same points. These abrupt deviations from the straight line do not occur at equidistant points: the intervals between them differ greatly; they average 1-400th of an inch in length. Under the lining membrane some few fibres may be distinguished taking a transverse course, others may be seen in an oblique direction, but the great majority are arranged longitudinally. The primitive fibre of cellular tissue is freely mixed with the peculiar fibres just described. The physiological fact that the lymphatics have the power of contracting and emptying themselves of their contents, has not been disputed; but with respect to the nature and form of the fibre in virtue of which they possess this faculty, there has been and still exists great uncertainty. No one can have examined the lacteal or lymphatic vessels in a recently killed animal without having observed the rapidity with which this system will empty itself of the fluid it contains; and if the trunk of the system be ligatured, it will be found that this power remains for an hour or more after death, as may be proved by puncturing the duct within this period below the ligature, or by puncturing a distended lymphatic, which will be instantly evacuated of its contents, and will refill again and again when pressure is made below the orifice.

Lymph hearts.—I must not here omit to allude to the pulsatile sacs or hearts belonging to the lymphatic system, discovered by Müller in frogs, toads, salamanders, and lizards, and by Panizza in serpents. In frogs, Müller describes two pairs, one situated just under the skin in the ischiadic region, the other more deeply seated over the third cervical vertebra. Their pulsations he describes as about 60 in a minute and not synchronous with those of the heart. The lower pair propel the lymph into the ischiadic vein; the upper, into the internal jugular.* I have seen these transparent pulsating bodies in the frog, where they may be easily exposed by removing the skin from either side of the rudimentary tail, but have not examined them sufficiently to pass any opinion upon them.

External to the fibrous tunic is situated a delicate and loose cellular tissue, which performs the same offices for the lymphatic, which the cellular tunic does for the artery and vein, viz. it conveys to it the vasa vasorum for its nutrition, and connects it to the surrounding tissues. The supply of nerve to the lymphatic has not hitherto been detected; there can however be no doubt but that it possesses its proper degree of sensibility, and its contractile power is in all probability regulated by nerve.

Fig. 47.



a and b, lymphatics laid open longitudinally to shew the arrangement of the valves in their interiors. (After Breschet.)

The valves of the lymphatics resemble in their mode of formation and in their appearance the same structures in the veins; they are however more frequent and more universal in the lymphatic system; indeed, in the more perfect animals they are found every where except in the incipient networks of this system. It has already been stated that in fishes and in some amphibious animals the lymphatic system is either entirely deficient in valves, or is only supplied with them in a partially developed state. The valve is composed of two semilunar flaps, so arranged that the reflux of the fluid within, forces them away from the sides of the vessel towards its centre, where the two flaps meet and completely close it, while the fluid passing in its proper direction

* Professor Weber has described one of these hearts in a large serpent, the pithon bivitatus. It measured nine lines in length, and four in breadth; it had an external cellular, a middle muscular, and an internal serous tunic. See Phil. Trans 1833, Müller's Archiv. for 1835, and Valentin's Repertorium, Bd. 1, p. 294. [Müller has subsequently described similar lymphatic hearts in the Chelonian Reptiles. Archiv. 1840, p. 1-4.—Ed.]

simply presses the flaps back against the sides of the vessel, and thus no obstruction is offered to its onward course. The flap of a valve consists of a fold of the inner coat of the vessel, which, where a valve is to be formed, ceases to line the vessel, and is reflected towards its interior; having reached half-way across, it is doubled upon itself, and returns to the side of the vessel, which it continues to line as if it had never been interrupted. The two layers of this fold adhere very firmly together so as to form a very delicate transparent semilunar flap. It presents a convex attached, and a straight or slightly concave unattached edge; the former corresponds to a semilunar line on the interior of the vessel, the horns of which look towards the trunks of the system, where the lining membrane was reflected from and returned to the side of the vessel; the latter to the line of doubling of the membrane upon itself; thus a little pouch is formed between the flap and the side of the vessel, which can only be filled by the fluid passing in one direction; and as a valve is constituted of two such pouches, when they are filled the vessel is completely closed. Some anatomists conceive that a lamina of fibrous tissue intervenes between the layers of the fold. Breschet, in his "Système Lymphatique," adopts Lauth's view of the structure of the valve. He describes the flap of a valve as composed of two parts, one thicker and situated at the base of the fold, the other forming the rest of the flap more thin and delicate. It is this latter part which he conceives is formed by

Fig. 48.

a, b, and c, lymphatic vessels inverted, giving three different views of the valves formed by the lining membrane. (After Breschet.)

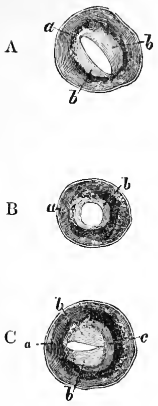
Fig. 49.

a, a front view of a valvular flap. *b*, a profile view of a lymphatic vessel and valvular flap; the lower half of the flap, or that nearest the base, is represented thicker than the rest. According to Lauth and Breschet, this thicker portion is formed of all the coats of the vessels; the thinner portion, of the lining membrane only. *(From Breschet.)*

a doubling of the lining membrane only, while the thicker part, near the base, he has assured himself is produced by a prolongation which the fibrous coat sends inwards between the folds of the inner tunic. I have not been able to verify this description of the structure of the valve, but I have distinctly observed circular constrictions in the more bead-like lymphatics seen in the neighbourhood of some of the lymphatic glands, into the formation of which the fibrous coat does appear to enter. On laying open one of these vessels previously distended with quicksilver and dried, opposite the external constrictions, which were numerous, and not more than a line apart, valvular folds, differing from those hitherto described, were seen to project into the interior of the vessel; they did not completely close its cavity, but left a circular or oval opening, through which the contents of the vessel might pass in either direction. These valvular constrictions resembled much the dried pyloric valve (*fig.* 50, B); and I am inclined to believe, from their thickness, that they contain circular fibres derived from the middle coat, by which during life they may be able to close their vessels as perfectly as the pyloric valve closes the communication between the stomach and duodenum. In very many places there occur two semilunar folds (*fig.* 50, A), apparently formed of the lining membrane only, like the flaps of the ordinary valves, from which they differ, however, in having their attached and unattached edges, as well as the flaps themselves, on the same plane, consequently not forming pouches, but a transverse though incomplete septum across the vessel. Each of these flaps extends only one-third across the vessel, and terminates by a crescentic edge, by which arrangement an elliptical opening is left in the central third of the vessel, between the two folds. This form of valve would appear to offer a partial obstruction to the passage of the lymph in either direction, as no provision is manifest by which these flaps would be made to fall against the sides of the vessel, either by the onward or retrograde course of its contents. I have frequently noticed a combination of the circular constriction with the semilunar flaps here described (*fig.* 50, C), by which mechanism, supposing the former to be endowed with a vital contractility, the latter might be brought in contact, so as completely to close the elliptical opening that would otherwise be left in the centre of the vessel.

At the entrance of the lateral branches into the thoracic duct, or of one lymphatic into another, a valve will be found, of a somewhat different form to those already described. It is composed of two semilunar flaps, seldom of equal size, arranged somewhat like the ilio-cœcal valve. One flap is occasionally so slightly developed that there appears but one large semilunar fold at the entrance of the vessel. At the union of some of these vessels with others, especially of those which lie nearly parallel with each other, no valve will be found, but simply a defined curved line, marking the orifice of communication. The valves in the lymphatic system are very closely set together. The distance between them varies much. In vessels of a line

Fig. 50.



Exhibits three forms of valves of very frequent occurrence in the lymphatics, especially in the neighbourhood of glands, and which are not described in works on Anatomy. (Taken from specimens prepared for the microscope.) Magnified ten diameters.

A. *a,* the interior of the vessel. *b, b,* the valvular flaps composed of the lining membrane only. The attached, the unattached edges, as well as the surface of these flaps, are on the same plane; they do not perfectly close the vessel.

B. *a,* the interior of the vessel. *b,* the valvular flap of a circular form, resembling the dried pyloric valve of the stomach; apparently composed of the fibrous as well as the inner tunic.

C represents a combination of the two former. *a,* the interior of the vessel. *b.* valvular flaps resembling those of A. *c,* a third fold resembling the circular fold of B.

in diameter they are frequently not more than a line apart, while in others of half that magnitude there may be an interval of an inch between them. It has been observed that they are more frequent and closer together in the larger lymphatics than in the smaller; this is not always the case; for instance, the lymphatics of the upper extremity, which are much smaller than those of the lower, have less intervals between their valves; and in the neck, where the vessels are still smaller, the valves are less distant apart. It appears to me that the valves are much more approximated to each other in the neighbourhood of the glands, and this observation applies to the vasa afferentia as well as to the vasa efferentia, but especially to the latter; from which circumstance the notion may have arisen, that the valves are more frequent the larger the vessel. The valves recur less frequently in the thoracic duct than in any other part of the system. It is not uncommon to find in this vessel an interval of two or three inches in extent without a valvular fold.

Mode of origin of the lymphatics.—The plan I have hitherto adopted in describing the lymphatic vessels has been to present to the reader, first, that which is most readily understood, because easily recognizable by our senses, and about which there could be little difference of opinion; but I have now to direct attention to a part of our subject which has hitherto baffled the efforts of all inquirers, viz. the mode of origin of the lymphatic vessels, concerning which the sight, aided by the most powerful glasses, has failed to supply us with satisfactory and demonstrable information. The numerous opinions and conjectures on this subject, only present us with so many instances, of the vain struggles of the human mind, to advance in a strict science of observation, beyond the limits assigned to our senses, and of the unwillingness, even in the philosopher and man of science, to acknowledge the weakness and limited range of his faculties.

When we consider the transparency of the coats of the lymphatic vessels, as well as of their contents, the small size of their secondary branches, and the numerous valves they every where present, we cannot feel surprised that their precise origin should be involved in much obscurity. From the opaque nature of the chyle, it might be imagined that while the vessels were distended with this fluid, the anatomist would be enabled to trace them to their commencing branches, but unfortunately, it is almost impossible to prevent the onward motion of the chyle in the vessels first receiving it, while the valves offer a complete barrier to any retrograde movement. Added to which, the opacity of the coats of the intestine renders it extremely difficult to follow these vessels from the peritoneal surface of the outer, to the villous surface of the inner tunic, even when distended with chyle. Transparency of the coats of the intestine may be obtained by drying, but the chyle becomes transparent at the same time. Various modes of investigation have been adopted by anatomists to overcome these difficulties, the principal of which it may be necessary here to mention. Injections of quicksilver or coloured fluids have been thrown into the arteries, by which means the injection has occasionally made its appearance in the lymphatic vessels: this result occurs, according to Panizza, in a particular organ in an animal of one species, while in another the experiment will succeed, not in the same, but in some other organ. Thus he succeeded in filling the lymphatics from the arteries, in the intestines of the dog and pig; in the liver of man, the horse, and dog; in the testicle of the dog and bull; in the penis and spleen of the horse. He was unsuccessful in the intestines of man, the horse, birds, the salamander, and the tortoise; in the liver of reptiles; in the spleen of man, the dog, and the pig; in the kidneys of mammalia and birds; in the penis of man and the dog.

Breschet is of opinion that injections by the veins pass more readily into the lymphatic system. I have now in my possession two preparations where the lymphatics have been accidentally injected from the veins; one in the mesentery of the turtle, the other in the kidney of man; and I have undoubtedly observed this occurrence much more frequently after injections by the veins than by the arteries. Every anatomist who has had much experience in injecting the lymphatic vessels has been incommoded by the injection passing unexpectedly into some large vein, and on looking for the communication, he has found the veins from a lymphatic gland conveying the injection into one of the nearest large venous trunks. This has occurred to me frequently in the human subject, where the common iliac veins and the cava inferior have received the quicksilver from the veins of the neighbouring lymphatic glands. I have also seen the same occurrence lately in the horse, and have the specimen shewing the fact now in my museum. It was these veins conveying the injection from the lymphatics into the venous trunks, which Lippi mistook for the vasa efferentia of the glands, and which induced him to publish his work describing many terminations to the lymphatic system in mammalia, hitherto unknown to anatomists. This error was the more excusable, inasmuch as his opinion appeared to be confirmed on the investigation being pursued by himself and others in the remaining classes of vertebrate animals, where various communications do actually take place between the lymphatic trunks and the veins.

Coloured fluids have been thrown into the cavity of the pleura and peritoneum in living animals for the purpose of bringing the lymphatic vessels into view, and of tracing if possible their extreme branches after absorption had taken place. In this way it is said that minute vessels anastomosing with each other, and forming a delicate net-work, may be made apparent on the surface of the serous membrane, and that the trunks of the neighbouring lymphatics may be seen filled with the coloured fluid. In post-mortem examinations also, the absorbent vessels have been observed distended with a fluid of a yellow or red colour, where effusions of pus or blood had taken place during life. In all these instances we probably first notice the injection in the larger lymphatic vessels which are easily recognized by their numerous valves, and on tracing these back to their commencing branches we only discover an intricate net-work of minute vessels apparently continuous with each other. It is exceedingly difficult to distinguish these from equally small branches of artery and vein, filled probably with the same coloured injection. You look in vain for the channel by which the injection has entered these vessels; no continuity of lymphatic with the minute twigs of the other sets of vessels can be detected; no open orifice belonging to either can be distinguished. Many anatomists have endeavoured to fill the commencing branches of the lymphatic system by forcing the injection, thrown into them, in a retrograde direction, and in fishes where there are no valves, with the effect of shewing very numerous lymphatic vessels destitute of orifices, but not so universally distributed as has been imagined.

Fohmann, Breschet, and others have simply made a puncture in the tissues, and by forcing quicksilver into the wound, have occasionally succeeded in filling a minute net-work of lymphatics. Cruickshank and Hewson employed ligatures to the thoracic duct, to the larger lymphatics, or simply round the limb immediately previous or subsequent to the death of the animal, for the purpose of distending the radicles of the system. Lastly, the microscope has been had recourse to by most observers. But the prevailing physiological opinions of the day have had more influence than all our anatomical investigations in determining our notions of the mode of origin of the lymphatic vessels. Indeed, so much has this been the case, that I shall find it convenient, in treating the subject of the origin of these vessels, to refer to the physiological views of the periods during which the successive opinions have been broached. The only other observation I shall make on entering upon this difficult and still obscure subject is, that the chyle seen on the coats of the intestine, contained in its proper vessels, so near to the villous tunic, has tempted anatomists to confine their observations perhaps too much to this one-absorbing surface, with the fixed intention of applying the information thus gained, to the whole system; whereas the fluid contained in the chyliferous vessels differs so much from that of the rest of the system, that it is not very improbable that the former which admit particles of matter should possess orifices, while the latter should receive its contents by imbibition without perceptible orifices, which, in fact, is the opinion held by two eminent physiologists, who have paid considerable attention to the subject, Magendie and Cruveilhier. The first opinion with respect to the mode of origin of the lymphatic vessels which I shall consider is that by open orifices.

Many investigators at various periods have attributed open orifices to the radicles of the lymphatic vessels; indeed, this has been the prevailing opinion till within the last few years. Asellius, the discoverer of that part of the system which is connected with the intestines, imagined that his "vasa lactea" commenced by open mouths from the interior of the intestine. His words are, "ad intestina instar hiant spongiosis capitulis." The first discoverers of the rest of the system, the "vasa lymphatica," did not attribute to them the function of absorption, but regarded them as destined to assist the veins in returning the circulating fluids to the heart. They supposed them, therefore, to be continuous with those arteries which admitted a colourless fluid only, while the veins in a similar way received their contents from the arteries conveying the red blood. The lymphatics properly so called were not considered to possess open orifices at their origin, until they were generally recognized as sharing with the lacteals, the important office of absorbing fluids, as well as conveying them towards the heart. It was not fairly established until the time of the Hunters, that these vessels formed part of the absorbent system, although Glisson and Hoffmann had expressed their opinion to this effect, a few years after the discovery of the lymphatic vessels. But to do justice to this part of our subject, it will be necessary to enter more fully into the Hunterian theory of absorption.

The Hunters, Monro, and their followers Cruickshank, Hewson, and Sheldon, conceived that the lacteals and lymphatics formed one great system of vessels by which alone absorption was effected in the living body, either for the purpose of collecting new materials, or for the removal of the old; consequently, that these vessels were essential agents in the growth and habitual nutrition of the structures; — that whenever any of the solid or fluid components of the body, whether of a healthy or morbid character, disappeared, their removal was effected by the lymphatic vessels; this included the ulcerative process, which they considered as exclusively carried on by these vessels. Many ingenious experiments were performed to disprove absorption by the veins. Fluids of various colours impregnated with musk and other odours were thrown into the intestines of living animals, and were afterwards detected in the lacteals, but not in the veins, and imbibition was considered impossible in the living structures. These views were generally received throughout Europe, and have been acquiesced in almost to the present day. Our phraseology, written or oral, whether in reference to Pathology, Physiology, or Anatomy, is evidently still imbued with them. This theory of the functions of the lymphatic system necessitated a corresponding anatomical disposition in the mode of origin, as well as in the general arrangement of these vessels. They were required to be universal for the purposes of growth and nutrition; wherever there was the artery to deposit, there must be lymphatic to absorb; and as imbibition was inadmissible, they were endowed, as a matter of necessity, with open mouths, by which they were said to commence from all serous and from all mucous surfaces, including the interior of all the visceral cavities, the serous linings of the arteries, veins, and even of the lymphatics themselves, the synovial surfaces of the joints; the surface of the skin, the mucous linings of the alimentary canal, of the aerial, urinary, and other passages, of the excretory ducts, and from the interstitial cellular tissue of the whole organism. It was admitted that the orifices of the lymphatic vessels could not be shewn; that they eluded our senses by their transparency and extreme minuteness; but on the villi of the intestine, the commencing lacteals were supposed to be detected, turgid with chyle, and their mode of origin by patent orifices was described by more than one anatomist. An analogous arrangement at their commencement was adjudged to the lymphatics, without any further investigation directed specially to these vessels. Cruickshank thus describes the appearance of the supposed lacteal orifices on the villi, seen in a female who died suddenly seven or eight hours after a full meal. "In some hundred villi, I saw a trunk of a lacteal forming or beginning by radiated branches. The orifices of these radii were very distinct on the surface of the villus, as well as the radii themselves, seen through the external surface passing into the trunk of the lacteal; they were full of a white fluid. There was but one of these trunks in each villus." He states also that Dr. Hunter examined them under the microscope, and counted as many as fifteen to twenty orifices to each villus. According to Lieberkuhn, the lacteal commences on the apex of each villus by one or more orifices leading to an ampullula situated near the apex of the villus, from whence one lacteal branch proceeds through the centre to the base of the villus. The ampullula, he states, is lined by a spongy cellular tissue, which he conceives is subservient to absorption. With respect to the orifices, his words are: "Quod autem unum saltem adsit foraminulum in cujusvis ampullulæ apice, certo examine mihi constat: interdum tamen, licet rarissime, plura ut in papillis mammarum, vidisse memini." Sheldon admits Lieberkuhn's description of the orifice of the lacteal vessel, and of the ampullated appearance of its commencement from the villus; but it appears to me, on looking at Sheldon's plates, and reading his description of the ampullulæ, that he as well as Lieberkuhn whose plates he has copied, have mistaken the mucous follicles of the intestines for the ampullated villi. Speaking of the ampullulæ, Sheldon says, "I have seen them of different forms, most commonly bulbous, as represented by Lieberkuhn. I have also seen a number of ampullulæ filled with chyle, sometimes forming clusters, as represented in plate I., while in other parts of the small intestines I have found them solitary, and projecting beyond the villi, as may be seen in several of the figures in plate I." Hewson has seen a net-work of lacteals as well as of bloodvessels on the villus, but no ampullulæ; he states that the orifices of the lacteals can only be discerned when the villus is rendered turgid and erect by the fullness of the bloodvessels. In reference to these orifices, he says: "It might be here objected that these were only lacerations of the villi, but I am persuaded they were not, from having, on repeatedly examining them, observed the pores or orifices very distinct and empty; whereas, were they lacerations, I think I should have seen the injection in them, as the villi were so much injected by it." These are the data upon which has been founded the opinion that the lacteals and lymphatics arise every where by open mouths. I have myself examined under the microscope the villi of various animals destroyed at different periods after a meal, for the purpose of detecting the mode of origin of the lacteal vessels. I have looked at them for hours together before and after the bloodvessels had been filled to great minuteness, but have never been enabled to discover orifices on the apices, or on any other part of the villus, and I can adduce the names of a host of modern observers of considerable celebrity, Rudolphi, Panizza, Haasse, Lauth, Fohmann, Breschet, Müller, Treviranus, and others, who deny the existence of any such orifices. Magendie and Cruveilhier conceive that the chyle must enter the lacteals by orifices on account of the material particles of which this fluid is composed; the lymph they suppose enters the vessels by imbibition through their coats.

Before alluding to the other opinions on the subject of the origin of the lymphatic vessels, it may be as well to premise the changes which have taken place in our physiological notions with respect to the function of absorption since the time of the Hunters and their immediate successors. Magendie has proved by numerous convincing experiments, that imbibition does take place in the living as well as in the dead body, not only through the coats of the lymphatics and bloodvessels, but through all the tissues. It has been equally well established by Magendie, Delille, Segalas, Mayer, Emmert, and other physiologists, that we can no longer exclude the veins from participation in the important function of admitting new and foreign matters into the animal system. With respect to imbibition, I will select one of many experiments instituted by M. Magendie. He exposed the external jugular vein in a dog, and having separated it from its cellular attachments, placed a piece of card underneath the vessel so as to isolate it from the surrounding parts. He now applied to the centre of the vein a watery solution of the spirituous extract of nux vomica. In four minutes the symptoms of poisoning made their appearance. If then it be admitted that imbibition takes place in the living textures, there can be no longer an absolute necessity for open mouths to the origins of the absorbing vessels, and it follows that the lymphatics cannot be the sole agents in the process of absorption.

I will now adduce some experiments conducted by different physiologists, proving the entrance of various substances into the living animal system by other channels than the lymphatics. Magendie divided all the structures of the hind leg of a living dog, with the exception of the femoral artery and vein, through which the circulation was carried on. He then inserted the upas tieuté poison into the foot of the mutilated limb. The animal was poisoned in the usual space of time required for this substance to take effect. He repeated the same experiment with the additional precaution of placing inert tubes into the artery and vein, and afterwards dividing these vessels, leaving the limb connected to the trunk by the tubes only, through which the blood passed to and from the limb; the same effect followed on the introduction of the poison.

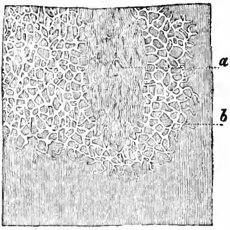
Mayer injected a solution of prussiate of potash into the lungs of an animal: in from two to five minutes after the injection, the serum of the blood, tested by a salt of iron, gave evidence of the presence of the prussiate of potash by the usual green or blue precipitate. It was detected in the blood long before it could be perceived in the contents of the thoracic duct, and in the left side of the heart before it appeared in the right. It was therefore evident that the pulmonary veins and not the lymphatics had first received the prussiate of potash and conveyed it to the heart. Segalas included a piece of intestine between two ligatures in a living animal, and tied all the bloodvessels leading to it excepting one artery; the lacteals were left uninjured and pervious; an aqueous solution of nux vomica was now injected into the piece of intestine and there secured for an hour without producing any symptoms, but on removing the ligature from one of the veins, the poison took effect in six minutes. The converse of this experiment was performed by Magendie and Delille. A portion of intestine of a living animal was included between two ligatures; the lacteals proceeding from it were ligatured and divided, the bloodvessels being left pervious. A solution of nux vomica thrown into this piece of intestine destroyed the animal in six minutes. Emmert applied a ligature to the abdominal aorta in a dog, and afterwards inserted prussic acid into the foot of one of the hind legs; no ill effects followed in seventy hours; the ligature was then removed, and in half an hour symptoms of poisoning appeared.

In addition to simple imbibition, Dr. Dutrochet has shewn that fluids situated in contact with animal membranes permeate them in obedience to certain laws. When two fluids of different densities are in contact with the opposite sides of a membranous septum, they both permeate it, but with different degrees of rapidity. The more rapid current takes place from the rarer to the denser fluid; to this he applies the term of Endosmosis: the slower current from the denser to the rarer fluid he calls Exosmosis. These remarkable powers must be continually in action in the animal machine, composed as it is of solids and fluids, and cannot for the future be lost sight of in considering the subject of the absorption and deposition of fluids in a living animal, or the arrangement of the structures by which these important functions are accomplished. Taking these facts into consideration, and bearing in mind the experiments above detailed, we are led to the conclusion, that the capillary bloodvessels and even other tissues imbibe indiscriminately fluids brought in contact with them, and apparently in obedience to the physical or mechanical laws regulating imbibition, rather than in virtue of any new and essential agency with which they may be endowed as living structures; while the lymphatic system is left in possession of a higher grade of absorption accompanied with an elective power (especially manifest in the lacteals) existing only with life, and if not entirely independent of mechanical or physical laws, at any rate frequently at variance with them; by this elective power they are enabled, to a great extent, to refuse materials injurious to the economy of the animal, and to select those alone which may be made subservient to the nutrition of the system.

These physiological considerations will prepare us better for the examination of the remaining theories on the mode of commencement of the lymphatic vessels. We shall next enter upon that which ascribes to them an origin from the cellular tissue. Fohmann has injected the lymphatic vessels from the cellular tissue, and most anatomists have remarked that when an injection thrown into the bloodvessels has extravasated into the cellular membrane, it has occasionally entered the lymphatic vessels. I have several times injected Fohmann's so called lymphatic cells of the umbilical cord, and have preserved a specimen shewing them, but cannot acquiesce in the opinion that they form a part of the lymphatic system. These cells, which readily receive the quicksilver introduced into a puncture made in the cord, vary in diameter from 1-100th to 1-250th of an inch, and communicate freely with each other; they have a very regular and organized appearance, but can only be injected after putrefaction has commenced. Fohmann describes them as situated between the lymphatics of the placenta, which terminate in them, and those of the fœtus, which commence from them. I have never succeeded in pressing the injection from the cells of the cord into the lymphatics of the fœtus or of the placenta. Treviranus conceives that the lymphatics everywhere commence by elementary cylinders of cellular tissue, and that in the villi of the intestines these elementary cylinders are so arranged as to have one of their extremities terminating in a lacteal vessel situated in the centre of each villus, while the other reaches the periphery of the villus, on the surface of which they present little vesicular projections, in whose centre he thinks he perceives a minute orifice. Arnold also observed a similar arrangement of the cellular tissue of the orbit into minute cylinders, which he supposed to be an incipient net-work of lymphatic vessels. Cruveilhier considers it probable that the cellular tissue and the serous membranes are formed of lymphatic vessels; and Mascagni makes a more sweeping assertion that all the white textures and the whole cellular web of the body is composed of these vessels.

The opinion that the lymphatic system commences by a plexus or net-work of vessels larger than the capillary bloodvessels, and which can always be seen by the unassisted eye when injected, appears to be the best supported by evidence, and to be that more generally received by modern investigators. These incipient plexuses are considered to be destitute of orifices either on the villi or elsewhere, and in this respect to resemble the peripheral branches of the arteries, veins, and excretory ducts, which, according to the more recent views in minute anatomy, no where present open mouths. The splendid injections of Mascagni, Fohmann, Lauth, and Panizza, shewing these vessels in various parts of the body, on the interior of mucous membranes, on the surface of particular portions of the skin, on the serous membranes, especially that part covering the solid viscera, on the lining membrane of the heart and bloodvessels, and of the excretory ducts of the glandular viscera, offer a body of evidence which can scarcely be resisted. In none of these situations can open orifices be discovered by the aid of the microscope or by means of urging on the injection. On the surface of the liver, where the lymphatics may be injected with great facility, by pressing in a retrograde direction the injection may be forced beyond the valves, and by continuing the force some extremely minute globules of mercury may be made apparently to pass through the coats of the vessels. Haase has also, by the same procedure, forced the mercury through a net-work of lymphatics on the surface of the skin; but these circumstances can hardly warrant the supposition of lateral organized pores. These primary networks of lymphatic vessels are said to be deficient in valves in some situations. The meshes of the networks are of various forms and sizes: sometimes they are nearly equal-sided, at others oblong or irregular; in some places the vessels are so closely set that the spaces between them can scarcely be seen; in others they are larger and very distinct. The plan adopted by Fohmann to display these vessels, though liable to some objections, appears to be the most successful. He pierces the part to be injected with a sharp-pointed lancet, held nearly horizontally, so as to produce a very superficial wound, the lymphatic net-work being generally nearer the surface than the capillary bloodvessels; into the wound thus effected the pipe of the mercurial injecting tube is inserted, and the quicksilver is made to enter some of the vessels opened in the incision, either by the weight of the column of the mercury or by urging it on with the handle of a scalpel. On the glans penis this method scarcely ever fails to fill the lymphatics, which are of large size. In the skin of the scrotum, and in the neighbourhood of the nipple, success will occasionally attend the attempt to shew these vessels; but in other parts of the integument, the endeavour has with me always been fruitless, so much so that I cannot help doubting their universal existence on the surface of the true skin. Breschet's description of a net-work of lymphatics brought into view by piercing the cuticle only, with a capillary tube of glass connected with a column of mercury, I am convinced is deceptive: his words are—

Fig. 51.



Shews an incipient plexus of lymphatic vessels. (From Breschet.)

a, the more superficial plexus formed of very minute valveless vessels. *b*, a deeper plexus formed of larger valveless vessels, which receive the contents of the former, and which terminate in lymphatic vessels armed with valves.

"Il consiste (ce procédé) à percer superficiellement le tissu cutané avec l'extremité d'un tube capillaire en verre ou en acier, de façon à n'intéresser que l'épiderme, pour arriver au réseau vasculaire situé entre cet épiderme et le chorion. On obtient ainsi l'injection de réseaux admirables de vaisseaux lymphatiques." I have frequently produced the appearance here alluded to in all parts of the body: a fœtus answers best for the purpose, but the proper lymphatics are never filled from these supposed net-works of lymphatic vessels. They are clearly nothing more than the spaces around the bases of the papillæ of the skin, from which, as putrefaction commences, the cuticle separates more readily than from their apices, consequently little canals are left around the papillæ, which communicate with each other and form a pretty exact resemblance to vessels filling rapidly as the mercury runs around the bases of the papillæ. The appearance can only be produced at a certain stage of putrefaction when the cuticle is about to separate. On removing the cuticle, the pretended vessels immediately disappear; but on the glans penis, on the scrotum, and on the skin of the nipple the removal of the cuticle will not disturb the net-works of vessels which may be there injected; moreover from these the lymphatic trunks can always be filled. I am also disposed to think, contrary to the received opinion, that the serous membranes do not universally present this superficial network of lymphatics; there are at any rate parts of these membranes where I have never seen these vessels injected, while there are others in which anatomists invariably succeed in shewing them; and for the mere purpose of absorbing the fluid secreted by the serous sacs, there appears to me nothing extraordinary in the supposition, that those portions of the membrane only which are most conveniently situated for the purpose should be endowed with the proper organization to effect it. The mode of procedure, however, adopted by Fohmann and others to display the incipient lymphatic net-works is open to serious objections, and calculated without great circumspection to lead into error. The capillary blood-vessels will often be implicated in the wound required to pierce the lymphatic net-work, consequently the injection may be found in the arterial and venous as well as in the larger lymphatic branches leading from the part. To succeed to any extent many punctures may be required, and in all probability some of these will conduct the injection into the three sets of vessels; but I have several times by the first puncture succeeded in injecting a net-work of vessels on the glans penis, which has conveyed the injection at once into the lymphatic branches on the body of the penis, and into these vessels only. The cellular tissue will also readily receive the injection, and where the cells are very small and uniform, as is the case with the umbilical cord, they resemble very much a net-work of vessels distended with quicksilver; and although Fohmann admits these to be cells, yet from their regularity he has been led to consider them a part of the lymphatic system. In the same category may be classed the supposed lymphatic cells of the cornea observed by Arnold and by Müller. The submucous cellular tissue also is frequently arranged in little cylindrical cells which communicate with each other, and these cells on receiving the mercury put on the appearance pretty exactly of a net-work of vessels, but lymphatic vessels are not found conveying the injection away from them to the nearest lymphatic glands, which I imagine should be the proof required before we admit any vessels or cells to belong to the lymphatic system, however beautifully displayed by our injections. The subserous tissue is open to the same remark, and I can hardly offer a better instance of what appears to me to be an error arising from this source, than by quoting Fohmann's own words in reference to what he describes as the lymphatics of the brain. "Les vaisseaux lymphatiques des enveloppes des masses centrales du systême nerveux sont très faciles à démontrer, surtout au cerveau et au cervelet. Lorsqu'on enfonce une lancette entre la piemère et l'arachnoïde, et qu'on insuffle le canal que l'on vient de pratiquer, on voit paraître un réseau lymphatique interposé entre ses deux tuniques, réseau formé de rameaux d'un calibre plus considérable que dans les autres tissus du corps; cependant leurs parois sont si foibles qu'elles se déchirent presque aussitôt qu'on y introduit le mercure." With respect to the universal net-work of lymphatics attributed to the lining membrane of the heart, and to that of the arteries and veins, I cannot admit, that the injections of a few minute canals with quicksilver on the lining membrane of the heart in the horse, by Lauth, and similar injections by Cruveilhier and Bonamy, can be received as demonstrative: the injection was not traced from them to a distinct lymphatic vessel, armed with valves and pursuing its course towards a lymphatic gland; these minute canals might have been capillary blood-vessels, or, as Breschet observes in his explanation of the plate which he gives from Lauth of these supposed vessels, "Nous pensons qu'ils sont uniquement constitués par des lacunes du tissu cellulaire."

In concluding what I had to say of the origin of the lymphatic vessels, a subject so inextricably mixed up with our preconceived physiological notions, I ought, perhaps, to offer some apology for advancing in an article of this nature any opinion peculiar to myself; I mean in reference to curtailing the extent to which the lymphatic system will be found to exist in the organism. My own mind has been forced to this conclusion after some years of attention to the subject, both from anatomical and physiological considerations.

It has appeared to me in the first place, that anatomists who have especially devoted their time to this interesting subject of late years, have not yet fairly freed themselves from the influence of the Hunterian views with respect to the part performed by the lymphatic vessels, as well as by the arterial capillaries, in effecting the growth and habitual nutrition of the structures. To support the Hunterian theory the lymphatic was required to be present with every molecule of the organization, there with open mouth (for imbibition in the living body was not admitted as possible) to remove the old material in order to make room for the new, which was supposed to be deposited by the open mouths of capillary arteries. Now, although physiologists no longer admit that the arteries any where terminate by open mouths, but consider all nutrition to take place by the transudation of the liquor sanguinis through the delicate tunics of the capillary bloodvessels, and although venous absorption, as well as lymphatic, is acknowledged to take place, consequently that the ubiquity of the lymphatic ceases to be a matter of necessity, still it appears to me that physiologists have not yet shaken off the old impression, that every particle of the organization must have its lymphatic vessel, and I cannot help thinking that the continuance of this impression is misleading us in our notions of the arrangement of the system.

There are also some additional anatomical considerations which have had their weight in leading me to the opinion that the lymphatic system is less extensive than is generally supposed. It is not, I believe, known to anatomists that the lymphatic vessels admit readily of dissection in their uninjected state; these vessels do not easily give way under traction, and by using the forceps to hold them, and a blunt but pointed instrument to detach them from the surrounding cellular membrane, to which they are but loosely attached, they may be dissected with equal facility as the cutaneous nerves, for which they are not unfrequently mistaken by the young dissector. I have in this way several times dissected the lymphatics of the upper extremity, from the glands in the axilla to the fingers, and in the lower, from the inguinal glands to the toes. In proceeding thus to trace these vessels, scarcely a single lateral branch can be detected in the leg and thigh, by which the supposed universal net-work of the surface of the skin could have been connected with the rest of the system. When the subcutaneous lymphatic vessels are injected with quicksilver, every anatomist must have remarked the absence of lateral branches; this has always been accounted for by supposing a valve at the termination of each lateral branch into the larger longitudinal vessels; but in dissecting these vessels in their uninjected state, the lateral branches if present ought to be met with, which is not the case. I am fully aware that Haase, and other investigators, have succeeded in getting the injection to pass in a retrograde direction from the subcutaneous lymphatics of the lower extremity into a net-work of vessels of small extent situated close to the surface of the skin: this has occurred to myself on two occasions, in the skin over the tibia, and in the inguinal region, but in both these instances it was in a portion of skin presenting a cicatrix; the net-work was circumscribed, and left the impression on my mind of an abnormal rather than of a normal condition of these vessels. The entire profession have adopted the notion that the process of ulceration is effected by the lymphatic vessels, consequently that, as every structure may ulcerate, so it must have its lymphatic vessel. But I may be permitted to ask pathologists to consider, whether they are not still influenced by the Hunterian theory, viz. that the countless open mouths of the lymphatics (which modern anatomists do not allow them to possess) effect the removal of the textures disappearing by ulceration, rather than by the few facts and observations bearing upon this important question. I would ask whether the occasional instances, of inflamed lymphatics containing pus, being found leading from an ulcerated surface, are sufficient to establish the opinion, that the whole process is effected by this set of vessels; or whether the occurrence is not more satisfactorily accounted for, by the supposition that the ulcerative process has implicated a lymphatic vessel, and that the pus has entered the vessel by an opening thus effected in its paries, or that the pus has been formed in the lymphatic itself, as the result of inflammation affecting its interior; more particularly when it is borne in mind, that the pus globule is much too large to have entered these vessels by imbibition, and that open mouths are denied to them. The parts of the body in which I have seen pus in the lymphatics, have been on the surface of the lung, on the mucous membrane of the intestines, on the penis when ulcers had occurred in these organs, also in the subcutaneous lymphatics after suppuration and sloughing of the cellular tissue,—situations in which every anatomist has seen lymphatics, and where the ulcerative or sloughing processes might readily have effected an opening into them.

The *lymphatic* or *absorbent glands*, called also *conglobate glands* by Sylvius, and *lymphatic ganglia* by Chaussier, are small fleshy bodies of a flattened form, rounded or oval in outline, varying from the size of a millet-seed to that of an almond; so situated in various parts of the body as to intercept the lymphatic vessels in their course towards the trunks of the system. They are generally clustered together, but occasionally are found single or isolated. The isolated glands are usually very small; the large ones clustered together. The lymphatic glands are well protected from pressure. In the limbs they are principally situated in the cellular spaces at the flexures of the joints, and enjoy the same protection as the main bloodvessels, close to which they are generally located. The loose cellular tissue in which they are for the most part imbedded, allows them great freedom of motion, by which they are enabled to elude pressure.

The lymphatic glands are most developed in childhood, least so in old age, and are intermediate in this respect in adult life. They are not found in Amphibia and Fishes, and in Birds only in the cervical region: intricate plexuses of large lymphatic vessels occur frequently in those animals which are destitute of lymphatic glands.

The colour of the lymphatic gland, depending apparently on the contents of its bloodvessels, is of a pale rose pink, resembling in this respect the colour of the salivary glands or of the cineritious matter of the brain; the exceptions to this observation will be found in the mesenteric glands while the chyle is passing through them, when they assume a whitish colour; the lymphatic glands in the neighbourhood of the liver and gall-bladder have been observed to possess a slight yellow tinge, but this is to be considered a post-mortem appearance. The black colour of the bronchial glands is remarkable and not easily accounted for; the lymph passing from the lung to them being always perfectly transparent and colourless.

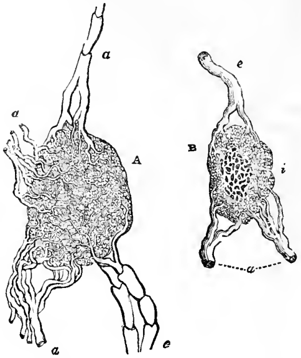
The lymphatic gland has a capsule of condensed cellular tissue, which surrounds it and firmly adheres to it, appearing to send cellular prolongations into its substance; the outer surface of this capsule is connected to the surrounding textures by a loose cellular tissue. The capsule appears to serve the purposes of conveying the bloodvessels to the interior of the gland, of isolating it from the surrounding parts, and of preventing its over-distension by the lymph conveyed to it.

The bloodvessels of the lymphatic glands are large and distinct; frequently more than one artery is traced to a gland; the returning veins do not generally correspond either in direction or number with the arteries. The veins are much larger, but have appeared to me fewer in number than the arteries.

Nerves of considerable size pass to the lymphatic glands and can generally be traced through them, from which circumstance it has been doubted whether any filaments are left in the gland; but if acute sensibility to pain from undue pressure or from disease be admitted as dependent upon a proper supply of nerve, undoubtedly they possess it. The exact mode of arrangement of the bloodvessels in the interior of the gland is not well known. After a successful injection of these vessels the gland assumes the same colour as the injection itself.

Our knowledge of the structure of the absorbent glands rests mainly upon the information obtained by throwing injections of mercury or coloured wax into the lymphatic vessels. In this mode of investigating their texture, the walls of the canals or cavities containing the injection, which appear, as in the kidney and testicle, to form the parenchyma of the organ, are compressed, and when dry become transparent. The arrangement of the minute bloodvessels on the lining membrane of these canals has not been sufficiently investigated, and until this has been effected, our knowledge of the structure and function of the lymphatic gland must be considered very unsatisfactory, and as consisting of little more than conjecture. The great point of controversy has been, whether the injection thrown into the gland by the afferent lymphatic vessels was contained in cells or in convoluted vessels, which if decided would throw but little light upon the office performed by the gland—a desideratum in physiology of considerable importance, and without which we are left in the dark at the very threshold of our investigations with respect to the first changes effected in the lymph and chyle, in advance towards sanguification. On examining

Fig. 52.



Lymphatic glands injected with mercury. (*After Mascagni.*)

A, gland injected and dried. *a, a,* vasa afferentia. *b,* vasa efferentia.

B, gland injected and laid open to show the apparent cells. *i,* apparent cells; *e,* vas efferens; *a,* vasa afferentia.

the glands thus distended with injections, the vasa inferentia are seen reaching the gland from various sources, and on their approach to it they may be observed to subdivide into extremely minute branches, which disappear by plunging into its substance: equally minute vessels may be observed emerging from its opposite side or surface, which soon unite to form the vasa efferentia of the gland; the gland itself, which is intermediate in position between these vessels, when injected, presents a granular surface, and at first sight an observer would generally conclude that he was looking upon minute cells filled by the injection; in making a section also into the substance of the gland and allowing the mercury to escape, the appearance on a superficial inspection is still that of cells; proceeding, however, with more attention to examine these supposed cells, especially after making a section as close to the surface of the gland as possible, by the aid of the microscope it will be evident that tubes closely set together and adherent to each other, have been laid open, passing in various directions, and in their interior many valvular constrictions and thread-like intersections may be seen; in fact the gland appears to be entirely composed of a convoluted vessel, the sides of which as they come in contact are firmly held together by cellular membrane derived from the capsule.

This convoluted tube forming the gland is not always cylindrical, but is occasionally dilated, and looks flattened near the surface where pressed by the capsule; the size of this tube is much larger than that of the branches of the vasa afferentia and efferentia, a fact that has been too much overlooked by anatomists, and which leads me to conjecture that these vessels enter and arise from its convolutions by open mouths; be this as it may, we know that the injection conveyed into the gland by the vasa afferentia readily passes from it by the vasa efferentia. I should not here omit to mention a circumstance already adverted to of considerable interest, viz. that the injection conveyed to a gland by an afferent vessel is occasionally received by the veins of that gland, and to all appearance without rupture or extravasation. The occurrence itself is admitted by all; but physiologists differ much in their explanations of the channel by which the injection has entered the vein. Some explain it by an extravasation into the cellular tissue from an injury by which both sets of vessels have been opened; others, who conceive that a minute net-work of lymphatics exists on the interior of the veins and arteries, will have no difficulty in imagining a rupture of this net-work; the vasa vasorum of the lymphatics, which may be distinctly seen on their interior after a minute injection, may be supposed to have given way and to have admitted the injection from the interior of the lymphatics. But these opinions will not explain why this communication should take place within the gland only, and invariably with the vein, never with the artery. The general opinion is that this communication takes place accidentally, and not by any real continuity of canal. Fohmann stands almost alone in asserting that a natural communication does exist between the lymphatics and veins within the glands, especially in those situations where in birds, reptiles, and fishes, the lymphatics have been proved to terminate directly in the veins. Fohmann even ventures an opinion as to the mode in which the lymphatic joins the vein; not, he conceives, by continuity of peripheral branches, but by an efferent lymphatic opening into the side of a vein before the latter emerges from the gland. Without committing myself to the exact mode of union, I must confess I agree with Fohmann that a natural communication does exist in some of the glands between the lymphatics and the veins. It has been observed hundreds of times. It has occurred to every anatomist who has engaged himself with the injection of these vessels; I have met with at least twenty such instances myself, while a similar communication between a lymphatic and artery within a gland has never been observed. I am entirely at a loss, therefore, to account for these occurrences without admitting a natural channel to exist between the one set of vessels and the other.

I have before observed that the exact arrangement of the bloodvessels in the interior of the canals of which the glands are constituted, is not known; but we are equally in the dark with respect to the vascular supply received by other minute tubes, such as the seminiferous, uriniferous, and lactiferous tubes, from the capillaries of whose lining membranes, however, we admit that their appropriate secretions are derived. As far, then, as organisation is concerned, there is nothing to forbid our ascribing a secreting function to the interior of the canals of the lymphatic glands, or of the lymphatic vessels generally. There can be little doubt but that the lymph and chyle undergo modifications in their passage through the absorbent glands, although we are not at present prepared to state the nature of that modification. It has been observed that the chyle included between two ligatures in its own vessel before it has reached a gland will not coagulate, although after it has passed the gland coagulation readily takes place. Müller remarks from this circumstance that the glands of the mesentery appear to have the power of changing part of the albumen of the chyle into fibrin. At any rate we are warranted, from the little we do know of the structure of the absorbent gland, in asserting, that the chyle and lymph collected from various sources must be mingled together in the glands, that they must be divided into extremely minute streams on their entrance into or exit from a gland, that they must be submitted to a great extent of surface of their containing vessels, and subjected to considerable delay in their passage through the gland. Mr. Gulliver's observations on the fluid contained in the absorbent glands would almost lead us to conclude that their proper office was to fabricate the peculiar globule of the lymph and chyle; my own observations on these fluids before and after reaching the glands would not bear out this opinion; but as I have next to consider the characters, physical, microscopical, and chemical, of these fluids, I shall shortly enter more fully into this subject.

Lymph is a transparent fluid, slightly opaline, of a light straw colour; its specific gravity is 1022·28, water being 1000·00; its odour, which is slight, varies, and is peculiar to each animal; it is alkaline, and has a saline taste. I collected in an ounce-phial about three drachms of lymph from a large lymphatic in the axilla of a horse, by inserting a small silver tube into it. In about ten minutes the whole had coagulated into a jelly-like mass; in half an hour a separation had taken place into a fluid and solid part: the latter formed a soft tremulous clot modelled to the form of the phial. A drop of this lymph placed on a piece of glass, and covered by talc, was submitted to inspection under the microscope, immediately after its removal from the vessel. A number of colourless spherical globules were observed in it having a granular surface, and precisely resembling those described by Mr. Gulliver as belonging to the mesenteric, lymphatic, and thymus glands. I am not aware whether Mr. Gulliver considers these globules as belonging exclusively to the glands, or whether he thinks them distinct from or identical with the lymph and chyle globule. My own observations lead me to state that they are found in the lymph or chyle before and after passing the glands, as well as in their transit through them. I am also disposed to assert that these globules remain colourless, and that whenever the lymph possesses a slightly red tint, it obtains that tint from the presence of blood corpuscules which have accidentally entered it. After coagulation had taken place, the lymph was again examined under the microscope, the globules were all found entangled in the clot; scarcely one remained in the transparent fluid. The clot, when disturbed, torn, and pressed, contracted to less than one-twentieth of its original bulk, and the few blood corpuscules it contained, being now approximated closely together in the contracted clot, gave it a slightly red tint. On examining the serum of this lymph under the microscope a week afterwards, when putrefaction had commenced, numerous exceedingly minute animalcules were seen diffused through it in active motion.

Müller gives an account of a fluid which makes its appearance after a portion of the skin of a frog is removed from the muscles; this fluid he considers to be pure lymph; he describes it as perfectly transparent and colourless, having a saline taste, but void of smell. Under the microscope he detected in it a number of colourless and spherical globules, about one-fourth of the magnitude of the elliptical blood corpuscule of the same animal, a few of which were unavoidably mixed with this lymph. Müller also describes what he considers to be human lymph, obtained from a small fistulous opening on a man's foot, the remains of a wound received on the instep; by pressure from the great toe towards the opening a transparent fluid could be made to transude; this fluid also contained colourless spherical globules, much smaller than the blood corpuscules. It, as well as that obtained from the frog, coagulated spontaneously, and appeared to possess the other properties of lymph. After coagulation had taken place in the fluid obtained from the man's foot, he observed that the globules were partly found in the clot, while some remained in the fluid surrounding the clot. In the horse's lymph examined by myself, all the globules were entangled in the clot.

The red colour of the contents of the thoracic duct, especially in the horse, has been remarked by most observers, but the cause of this redness has not been well ascertained. Breschet says, in his Système Lymphatique, page 160: "Ce qu'il eût été intéressant surtout de déterminer, c'est si la matière colorante qui teint quelquefois le chyle, et même la lymphe, y est dissoute, ou si elle affecte soit toujours, soit au moins quelquefois, la même disposition que celle des globules du sang." I have frequently examined microscopically this reddish fluid of the thoracic duct, and have invariably found it to depend upon the presence of red corpuscules of precisely the form and size of those of the blood. I believe that these red corpuscules are extraneous to the lymph, that their presence is accidental, and should be considered as a post-mortem occurrence. I would attribute their existence in the contents of the thoracic duct to the circumstance that very many lymphatics must be divided with the other structures, before the thoracic duct or indeed any large lymphatic can be exposed; these divided lymphatics must necessarily have blood applied to their cut extremities; the vessels being open receive the blood corpuscules, and convey them from all parts to the thoracic duct. This is not mere conjecture. I have seen the blood enter the divided vessels in the following experiment made for the purpose. On the under surface of the liver of a horse recently killed I observed some large lymphatics filled with a beautifully transparent fluid. I made an incision into the liver over these vessels, of course dividing them, and in a few seconds saw them conveying a reddish fluid towards the thoracic duct.

The lymph bears great resemblance to the liquor sanguinis both in its physical and chemical characters. Müller, who had observed that the blood of frogs will not coagulate when they are kept out of water in summer for eight or ten days, mentions the coincidence that when this is the case, the transparent fluid which he obtained by removing a piece of skin from a living frog, and which he conceived to be the lymph of the animal, was also incapable of spontaneous coagulation.

Leuret and Lassaigne give the following analysis of lymph obtained from the lymphatics of the neck in a horse:—

Water	925
Albumen	57·36
Fibrine	3·30
Chloride of sodium; Chloride of potassium; Soda; Phosphate of lime	14·34
	1000·00

Salivary matter, ozmazome, carbonates, sulphates, muriates, and acetates of soda and potash, with phosphate of potash, have in addition been detected in the lymph by Tiedemann and Gmelin.

Chevreul analysed some lymph procured by Magendie from the thoracic duct of a horse after five days' abstinence. Its composition was as follows:—

Water	926·4
Fibrine	4·2
Albumen	61·0
Muriate of soda	6·1
Carbonate of soda	1·8
Phosphate of lime; Carbonate of magnesia; Carbonate of lime	5
	1000·0

M. Magendie and M. Collard de Martigny have examined the lymph in animals, after depriving them altogether of sustenance; up to the tenth or twelfth day the lymph was found in greater abundance, appeared to have more of the red tinge, and to be more consistent; but after this period it diminished in quantity, became more watery and had less of the rose tint. The latter physiologist rejects altogether the opinion entertained by some, that the lymph would assume a redder colour the longer the animal fasted.

The lymph is said to coagulate more readily after passing through the lymphatic glands, and the nearer it approaches the thoracic duct. I have not found this to be the case in so marked a degree as has been stated. I have collected lymph from the lymphatics of the intestines before they reached the glands, and from various parts of the body in which no glands are situated, and have invariably found the fluid to coagulate spontaneously, although if in small quantity it may shortly return to the liquid state.

The fluid contained in the lacteal vessels in Mammalia is of a white colour like milk, and is called chyle; it has a marked saline taste, is slightly alkaline, and has no perceptible odour. I have now before me several specimens of recent chyle collected carefully from the lacteal vessels, before they reach the glands, from the glands themselves, from the vasa efferentia of the glands, and from the thoracic duct. These specimens were taken from a donkey killed for the purpose, seven hours after a full meal of oats and beans. About half a drachm was obtained from the vasa inferentia, and a drachm from the mesenteric glands themselves in watch-glasses; from the vasa efferentia about three drachms were procured in a test-tube, and from the thoracic duct in a phial nearly an ounce. All were of a pure milk-white colour except that from the thoracic duct, which had a slight pink tint. They all jellied spontaneously in from five to ten minutes; that from the vasa inferentia again liquified in about half an hour, and remained in this state; on other occasions I have known it retain its solidity. I have also seen the chyle from the glands, and from the vasa efferentia, return to the liquid state after having been coagulated for a short period. I have observed the same occurrence in lymph before and after it had traversed a gland. In about half an hour, with the exception already noticed, these specimens of chyle separated into a kind of serum and clot, the latter forming by far the greater portion, at least four-fifths of the whole. This clot, however, on being broken up and pressed, contracted to one-twentieth part of its former bulk; both the serum and the clot retaining their white colour. In the specimen obtained from the thoracic duct the pink tint was confined to the clot, and the serum was whitish or whey-coloured. It ought here to be stated that chyle, before it has reached the receptaculum, will not always separate into a fluid and solid portion, but will remain of the consistency of a soft white jelly, from which, however, by breaking it up, a white fluid may be obtained.

I find great error and confusion in the descriptions hitherto given of the microscopical appearances of the chyle. Müller and Breschet both state, that the white colour of the chyle depends upon its globules, which they then proceed to describe; they both quote Prevost and Dumas as estimating the diameter of the chyle globule at 1-7199th of an inch, or about half that of the blood globule in man. Müller says that in the cat he finds them of the same size as the blood corpuscules, and in the rabbit some of them were larger; in the calf, the dog, and the goat he found them much smaller than the blood corpuscules of the same animal. Breschet, in his work on the lymphatic system, published in 1836, acknowledges the unsatisfactory state of our knowledge with respect to the globules of the chyle and lymph. Tiedemann and Gmelin, in their elaborate work on digestion, distinctly state they consider the white colour of the chyle to depend upon fatty particles, which form a sort of emulsion with the serous portion of the chyle. Mr. Gulliver has given by far the most correct description of the microscopical appearances of the chyle that I have met with; he is the first who has noticed the extremely minute particles which constitute the characteristic microscopical appearance of the chyle, for the larger globules, noticed by most observers, are found also in the lymph. Mr. Gulliver has not, however, corrected the statement of Müller, Breschet, and others that the white colour of the chyle depends upon these larger globules; but I doubt not he would acquiesce with me in opinion that the white colour depends altogether upon the more minute particles. With these preliminary remarks I shall proceed to describe the microscopic characters of the chyle from my own obervations.

Every one is aware that the lacteals, when not conveying chyle, contain a transparent fluid not to be distinguished by the eye from the lymph of other parts of the system; to this fluid is added, during the digestion of a meal, myriads of extremely minute particles, twenty or thirty times less in size than the lymph or blood globules of the same animal, and which can scarcely be distinguished by a glass of less power than one-eighth of an inch focus, upon which undoubtedly the white colour of the chyle depends; when these particles are very numerous, the chyle is perfectly white and opaque; when less so, it will be whey-coloured or semitransparent. These particles are peculiar to the chyle, and I have been in the habit, for the last two years, of calling them the chyle granules, in contradistinction to the globules of different kinds which are also found in this fluid. The chyle granules, when allowed to dry on a piece of glass, measure from 1-20,000th to 1-10,000th of an inch in diameter, and are larger and more distinct in carnivorous than in graminivorous animals. The most remarkable peculiarity, which I believe I am the first to notice, of these chyle granules, is their continual vibratory or oscillatory motions. On viewing under the microscope a drop of chyle taken from the lacteal of a carnivorous animal, and placed between a piece of glass and talc, the motions of the chyle granules will be seen to be so constant and ceaseless, that the observer would at first sight be led to consider the chyle as a moving mass of restless animalcules; but on noticing the limited range, as well as the sameness, and apparent want of object, in these to and fro movements, he will probably feel inclined to attribute them to some unknown attraction and repulsion, influencing inert and unorganized particles. It is assuredly a striking fact, and one fraught with great interest, that the new molecules on their first introduction into the living system, should possess one of the most conspicuous attributes of vitality, viz. motion.* Mr. Ancell, who has paid great attention to the animal fluids, has frequently examined these moveable granules with me, and is inclined to consider their motions, as indicating the first obvious impress of vitality which the new material has received from its association with living matter. Besides the granules, there exist in the chyle numerous spherical globules colourless and granular on the surface, averaging 1-5000th, but ranging between 1-3000th and 1-7000th of an inch in diameter, resembling in every particular the lymph globule, with which they are probably identical. These globules I conceive are not derived from the interior of the intestine as some have supposed, nor from the glands, as I presume is Mr. Gulliver's opinion, but I would rather say are formed in the chyle and lymph by the aggregation of similar particles, probably fibrinous. Globules of oily or fatty matter are also found in the chyle; these may be readily distinguished by their circular and even outline, by their smooth and apparently flat surfaces, and by the great variety of their size, some being as small as the chyle granule, while others exceed the globule in diameter; in many respects they resemble the milk globule in appearance. Blood corpuscules will of course be frequently seen mixed with the chyle, as it is exceedingly difficult to collect it free from them. In the chyle the blood corpuscule loses its circular outline, its ordinary flattened form, its concave or cupped surface, and assumes a corrugated or wrinkled appearance, a spiked or serrated edge; the blood corpuscules, when thus corrugated, are less in diameter than the surrounding chyle globules, and have frequently been mistaken for them. On examining the blood taken from a living animal after a recent flow of chyle into it, this appearance of the blood corpuscule will also be readily distinguished. The corrugations alluded to on the blood corpuscule may be mistaken for spots on it; and when the corpuscule is revolving or vibrating, they may even appear like particles moving within it. I was for a short time misled by this deceptive appearance into the belief that the chyle granule, when received into the blood, entered the envelope of the blood corpuscule to form its nucleus. This erroneous notion, however, was soon corrected on finding that other fluids produced the same appearance in the blood corpuscules. It will be observed then, that I am induced to think that the chyle is never perfectly free from lymph; that in fact the lymph is termed chyle when it is rendered white by the addition of the moveable chyle granules from the interior of the intestine, to which are added from the same source the oily or fatty particles.

* [Wagner has depicted in his Icones Physiologicæ minute granules, which he designates "Moleculæ minores, cujusmodi in liquore chyli natant, procul dubio chyli granula futura." Tab. xiii. fig. 11.—Ed.]

If the clot and serum of the chyle be examined separately under the microscope, they will both be found to contain the chyle granule in sufficient quantity to render them white; the chyle globule, or any blood corpuscule that the specimen may have contained, will be entangled in the clot, while the oily particles will be principally found in the serum. If the coagulation has been incomplete, or the specimen has been agitated, some chyle globules and blood corpuscules will of course be mixed with the serum.

The chyle has been analyzed by Reuss and Emmert, by Vauquelin, by Marcet, Prout, and Brande, by Leuret and Lassaigne and by Tiedemann and Gmelin, but in a science so rapidly progressive as chemistry it is desirable to adduce the most recent information bearing on the subject. I shall therefore select the analysis given by Berzelius, (taken from the translation of his treatise on Chemistry by Me. Eslinger, published at Paris in 1833,) who adopts some of the opinions of Tiedemann and Gmelin, and with whose analysis of the chyle his pretty exactly agrees.

In 100 parts of chyle, taken from the thoracic duct of a horse during the digestion of a meal of oats, he obtained, after breaking up and pressing the clot, 96·99 parts by weight of serum and 3·01 of clot: the former was reduced by desiccation to 7·39 parts and the latter to 0·78; consequently, after evaporation, the proportions in 100 parts stood thus—

Desiccated clot	0·78
Desiccated serum	7·39
Water	91·83
	100·00

The dry clot softened when digested in distilled vinegar, but without being dissolved by it to any perceptible extent. A small quantity of a brownish-yellow oil was obtained from it by the action of boiling alcohol.

One hundred parts of the desiccated serum contained—

Brown fatty matter	15·47
Yellow fatty matter	6·35
Osmazome, lactate of soda, and chloride of sodium	16·02
Extractive matter soluble in water, insoluble in alcohol, with carbonate and a little phosphate of soda	2·76
Albumen	55·25
Carbonate with traces of phosphate of lime	2·76
	98·61

It has been generally stated and believed that a sufficient quantity of chyle for chemical analysis could not be obtained from the lacteals before they reached the thoracic duct, consequently, that which has hitherto been submitted to chemical examination has been taken from the trunk of the system, where it must of necessity have been mixed with a greater or less quantity of lymph; the comparison therefore between chyle and lymph has never been fairly instituted. Regretting with others the deficiency in our knowledge of the relative compositions of these important fluids, which, though derived from such different sources, enter in combination the already circulating blood, I performed some experiments, which need not here be described in detail, for the purpose of ascertaining the quantity of chyle that might be procured from the vasa efferentia of the mesenteric glands, and found that by a little care and contrivance as much as half an ounce of perfectly pure chyle might be procured from a horse after a full meal. I now applied to Dr. G. O. Rees, well known to me as an able and zealous investigator of the too much neglected science of animal chemistry, and requested him to undertake the analysis of the unmixed chyle and lymph, and to institute the desired comparison between them. Dr. Rees kindly acquiesced in my proposal, and has published the result of his inquiry in one of the late numbers of the London Medical Gazette, from which I transcribe his analysis with some of his observations, the whole of which are well worthy of perusal. The fluids in question were procured from a donkey, killed seven hours after a full meal of oats and beans.

Analysis of chyle and lymph before reaching the thoracic duct, by Dr. G. O. Rees—

	Chyle.	*Lymph.*
Water	90·237	96·536
Albuminous matter	3·516	1·200
Fibrinous matter	0·370	0·120
Animal extractive matter soluble in water and alcohol	0·332	0·240
Animal extractive matter soluble in water only	1·233	1·319
Fatty matter	3·601	a trace.
Salts. Alkaline chloride, sulphate and carbonate, with traces of alkaline phosphate, oxide of iron	0·711	0·585
	100·000	100·00

Dr. Rees describes the albuminous matter of chyle as possessing a dead-white colour, which he attributes to the admixture of a substance of a peculiar character, and upon which he conceives it probable that the white colour of the chyle depends. Will further investigation prove this peculiar substance to be derived from the chyle granule? or is the chyle granule formed of a combination of this substance with fatty matter?

This peculiar matter, Dr. Rees states, is readily obtained by agitating chyle with æther, when the mixture speedily separates into three distinct strata, the centre stratum being the substance in question; a similar matter, he observes, may be obtained from saliva by treating it in the same way. He found it to react as follows:—

"It was insoluble in alcohol, both hot and cold—insoluble in æther—miscible with water, and soluble in liquor potassæ. When it had been dried on platinum foil, the addition of water made it pulpy, and it was found still to be miscible with that fluid, from which, however, it separated in flakes on the addition of diacetate of lead."

I have now examined each part of the lymphatic system in detail, and on reviewing it as a whole, with the mind fully emancipated from the old erroneous views in physiology, and with a full conviction of the truth of the modern discoveries with respect to imbibition, endosmosis, and exosmosis, including venous absorption, as established by Magendie, Dutrochet, Segalas, Delille, and others, and admitted by Müller, Panizza, Fohmann, Lauth, Breschet, and all the modern investigators in this interesting and intricate field of inquiry, in which I regret not to be able to mention the name of one of our own countrymen since the time of Cruickshank, Hewson, and Sheldon —in bringing, I say, with our present improved state of knowledge in physics and physiology, the mind to bear upon the subject of the lymphatic system, it appears to me that we are justified in materially modifying our opinions, both with respect to the functions exercised by this system of vessels, as well as with regard to its anatomical arrangement, which has been made to depend so much upon the preconceived physiological notions respecting it. I venture then to suggest that we are going too far in attributing to the lymphatic (since the veins also absorb) the important and universal function of interstitial absorption of the old material, previous to the deposition of the new, in the process of growth and nutrition; that it is without sufficient proof that we admit the ulcerative process to be carried on solely through the agency of the lymphatic system, or that the removal of all morbid growths or depositions is effected by the one order of absorbent vessels unassisted by the other; and indeed that there would be nothing repugnant to sound reasoning, or at variance with the present improved state of our knowledge, were we to confine the functions of the lymphatic system more within the bounds ascribed to the lacteal vessels during the process of digestion, viz. to select and prepare nutritious materials for the purpose of sanguification, and to deposit them in the already circulating current.

Descriptive anatomy.—I now proceed to describe the exact course which the lymphatic vessels take in the different parts of the body, the position and number of the absorbent glands which they traverse, and the precise direction, mode of commencement, and termination of the two principal trunks, into which they pour their contents.

This part of our subject, the descriptive anatomy, neither requires nor admits of that rigid exactness which is absolutely necessary in tracing out the ramifications of the blood-vessels. In the first place, the surgeon, in the performance of his operations and in the treatment of wounds, scarcely finds it necessary to take the lymphatic vessels into consideration. To relieve the stricture in strangulated femoral hernia, he unsparingly divides the principal lymphatics and glands in the inguinal region. In the next place these vessels vary so much in number, and consequently in position in different individuals, while there exist so many parts, where their presence is rather presumed than demonstrated, that a general outline of their course is all that can be required or depended upon. In the distribution of these vessels two principal objects are specially provided for; the conveyance of the lymph to its appropriate glands, and afterwards from them to the two trunks of the system. We, consequently, first notice an evident tendency of the vessels from the structures in which they take origin towards the glands which intervene between them and the trunks of the system; secondly, their necessary course from these glands to the trunks themselves.

With this key to the distribution of these vessels, I propose to describe, first, the position of the glands, then to treat of the trunks of the system; and, lastly, having these two fixed points, to trace the vessels throughout their course.

In the lower extremities the conglobate glands are chiefly found in the inguinal region, where they are divided into a superficial and deeper seated cluster; a few small glands are situated in the popliteal space surrounding the bloodvessels. We rarely meet with one between the popliteal space and the inguinal region, and they are only occasionally met with below the knee, and then isolated and extremely small. In the upper extremity the large and clustered lymphatic glands are only found in the axillary space; a single gland is generally located just above the internal condyle of the humerus; below this point a distinct gland is rarely met with.

In the cervical region the principal lymphatic glands are situated in two cellular intervals, found at the upper part between the omo-hyoid and sterno-cleido-mastoid muscles, and below between the latter muscle and the trapezius. The glands in these positions are ranged in a line so as to form a sort of chain of glands, hence the term glandulæ concatenatæ as applied to them.

On the head and face the glands are few, small, and isolated. One may be pretty constantly met with behind the ear over the mastoid process of the temporal bone, another in front of the ear in the neighbourhood of the parotid gland. One or two will be found under the margin of the lower jaw, both in the median line and also more laterally situated. A small lymphatic gland will usually be distinguished amonst the numerous but small buccal and labial glands.

In the cavity of the cranium no lymphatic glands have been discovered, but in the abdominal and thoracic cavities they are very numerous. In the abdomen they are chiefly situated in the neighbourhood of the larger bloodvessels. In the pelvic region they form clusters, or rather chains of glands accompanying the external, internal, and common iliac vessels, and in the lumbar region they are similarly arranged on either side of the aorta, as high as the point of origin of the superior mesenteric artery.

The absorbent glands which intercept the lacteals in their course towards the receptaculum chyli are large and numerous; they are situated between the folds of the mesentery, and accompany the trunk and some of the branches of the superior mesenteric artery; they are usually termed mesenteric glands. The remaining lymphatic glands of the abdominal viscera, though numerous, are smaller and more isolated; they will generally be found close to the arteries of the viscera to which they belong, and consequently between the folds of the peritoneum. Of this description may be considered those accompanying the hepatic and splenic vessels: the coronary and gastro-epiploic arteries of the stomach, the small glands of the mesocolon or epiploon, those associated with the renal or spermatic arteries.

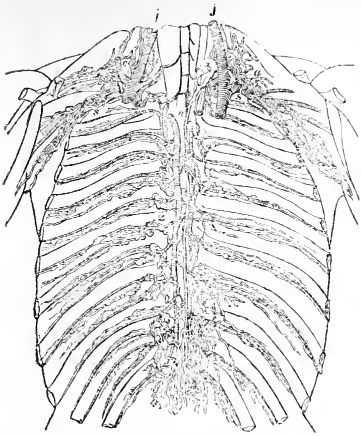
The largest absorbent glands of the thoracic cavity are those which receive the lymphatics from the lungs; they are situated at the roots of the lungs, pretty closely attached to the bronchi; they are generally of a dark colour and are called bronchial glands. Those associated with the lymphatic vessels of the heart are few and small; two or three may generally be noticed of the size of millet-seeds on the aorta and pulmonary artery, where these vessels are invested by the pericardium. In the posterior mediastinum close to the thoracic duct three or four large lymphatic glands are usually met with, as well as several smaller ones in the intercostal spaces, not far from the thoracic duct. In the anterior mediastinum also some small glands may be observed imbedded in loose cellular tissue in the neighbourhood of the internal mammary vessels. Occasionally a small gland may be seen on the convex surface of the diaphragm.

In the substance or parenchyma of the different organs no lymphatic glands have been detected. They have never been seen in the brain, spinal marrow, in the lungs, liver, spleen, kidney, or testicles, in nerve, muscle, or bone.

Having given this general outline of the position of the lymphatic glands, I shall now proceed to describe the trunks of the system.

The thoracic duct, (*fig.* 53,) or principal trunk of the lymphatic system, generally commences on the body of the second lumbar vertebra pretty exactly in the median line, concealed behind the root of the right emulgent artery, bounded on the right by the right crus of the diaphragm, and to the left by the aorta, to which it is connected by cellular tissue. It may be said to be formed by the union of the lymphatics of the lower extremities with the trunks of the lacteals proceeding from the intestines. At the conflux of the principal vessels from these three sources,—and there may be more than one from each,—a dilatation is sometimes found, which has been called the *receptaculum chyli*. From the body of the second lumbar vertebra the thoracic duct ascends into the thorax between the aorta and vena azygos. In the thorax it is situated behind the right pleural fold of the posterior medias-

Fig. 53.



The thoracic duct and right lymphatic trunk. (*After Mascagni*)

b, The right lymphatic trunk.
c, The trunk of the cervical lymphatics entering separately the internal jugular vein.
s, Subclavian vein.
j, Internal jugular vein.
z, Vena azygos.

tinum, having the aorta to its left, the vena azygos to its right, and the œsophagus in front. In this position it ascends as high as the fourth or third dorsal vertebra, at which level, continuing its course upwards, it turns from right to left, passing behind the descending portion of the arch of the aorta, above which it appears a little external to the root of the left subclavian artery, from whence continuing to ascend it passes between the latter and the left common carotid artery, lying on the longus colli muscle; it now mounts into the cervical region in front of the vertebral artery and vein to the level of the seventh cervical vertebra, opposite to which it begins to form a curve, first forwards and outwards, then downwards and inwards, striding over the subclavian artery to reach the angle of union between the subclavian and internal jugular veins, at which point it empties itself into the venous system either by one or more branches.

The thoracic duct is not uniform in diameter throughout its course; besides the occasional dilatation at its commencement, it generally presents another on the fourth dorsal vertebra just below its passage behind the descending thoracic aorta. Its narrowest part usually corresponds to the sixth or seventh dorsal vertebra. The duct is frequently tortuous and rarely single throughout. It often splits into two or more branches, which after a longer or shorter course reunite; this division and reunion may be two or three times repeated, and it may ultimately terminate by two or three branches instead of one.

The principal irregularities in the arrangement of the thoracic duct, which have been recorded by anatomists, are—a double duct, one terminating in the left, the other in the right side of the neck; a bifurcation of the duct at a higher or lower level, one branch terminating in the angle of union of the subclavian and internal jugular veins of the left side, the other emptying itself either into the corresponding point on the right side or joining the right lymphatic trunk, close to its termination; a single trunk terminating altogether on the right side of the conflux of the internal jugular and subclavian veins, in which case a short lymphatic trunk is found on the left side similar to that which usually exists on the right, constituting a partial lateral inversion or transposition confined to the trunks of the lymphatic system.

Besides the lymphatics of the lower extremities and the lacteals, the thoracic duct receives directly or indirectly the lymphatics of the remaining abdominal viscera (except a few from the right lobe of the liver), those from the exterior and interior of the lower half of the trunk; also the lymphatics of the left upper extremity, and left side of the head and neck, those from the left lung, the left side of the heart, and from the exterior and interior of the left upper half of the body.

The right lymphatic trunk nearly equals the thoracic duct in diameter; it is, however, not more than half an inch in length. Its situation is in the neck at the level of the lower edge of the seventh cervical vertebra, where it will be found lying upon of the subclavian vessels close to the inner edge of the scalenus anticus muscle, and opposite to the union of the subclavian and internal jugular veins, at which point it terminates in the venous system.

The right lymphatic trunk receives the lymphatics of the right upper extremity and of the right side of the head and neck, those from the right lung and right side of the heart, some few from the right lobe of the liver, and from the exterior and interior of the right upper half of the body.

Some of the principal branches which ordinarily empty themselves into the right lymphatic trunk occasionally terminate separately in the internal jugular or subclavian veins close to their junction. When these vessels all enter the veins separately, then the right lymphatic trunk is said to be deficient.

Having described the position of the trunks of the lymphatic system as well as the situations of the conglobate glands in the various parts of the body, I now proceed to trace the vessels themselves.

I shall commence with the description of the lymphatics of the lower extremities, as being the most remote from the trunks of the system. They are divided, as in all other parts of the body, into a superficial and deep-seated set, which latter accompany the principal bloodvessels. They are associated successively with the digital arteries, the internal, external plantar, and dorsal arteries of the foot; in the leg with the anterior, posterior tibial, and fibular vessels.

Fig. 54.

Superficial lymphatics of the lower extremity. (After Mascagni.)

b, Inguinal glands.
c, Commencing branches.
d, *e*, *f*, *g*, The continuations of the vessels similarly marked in the former wood-cut.

At least two lymphatics, which are united frequently by short branches crossing from one to the other, accompany each of these arteries, and all are ultimately conducted by the blood-vessels to the popliteal glands, in which they terminate. The vasa efferentia of these glands, from two to six in number, entwine around the popliteal and femoral vessels, having frequent communications with each other by short cross branches, until they reach the inguinal region, where they terminate for the most part in the deep-seated cluster of inguinal glands; one or more, however, may reach the superficial glands or even those accompanying the external iliac artery above Poupart's ligament. The deep-seated lymphatics in their course are joined by branches which have accompanied the principal ramifications of the bloodvessels; they also at various points form communications with the superficial lymphatic vessels.

The superficial lymphatics of the lower extremities may be divided into two groups; one consisting of numerous vessels which follow more or less the course of the saphena major vein and terminate in the inguinal glands; the other composed of but few vessels, which, accompanying the saphena minor vein, join the popliteal glands. The latter take origin from the dorsal surface of the little toe and from the outer edge of the dorsum and sole of the foot; they proceed with the branches of the saphena minor vein in the direction of the external malleolus, from thence to the outer edge of the tendo Achillis, where they glide with the vein under the fascia of the leg to reach the centre of the gastrocnemius muscle, between the heads of which they dip to join the popliteal glands. The superficial lymphatics which accompany the saphena major vein commence on the dorsal surface of the toes, where they communicate with the digital lymphatics. On the dorsum of the foot they ascend in from three to six branches; the most internal mount over the internal malleolus with the branches of the saphena major vein to the inside of the knee; the most external pass over the external malleolus and outer side of the leg, at a higher or lower level however, they are directed inwards and pass over the spine and inner surface of the tibia to join the former, at the inner side of the knee; those from the centre part of the dorsum of the foot ascend in front of the tibia; these also soon tend inwards to be associated with the rest.

Another set take origin from the sole of the foot and proceed upwards on the back of the leg superficial to the fascia, having communicated freely with the lymphatics accompanying the saphena minor vein. These also sooner or later turn inwards to gain the inside of the knee. From these sources some twelve or fifteen branches may be enumerated, which continue to ascend on the inside of the thigh with the saphena major vein. Some few pass under the fascia lata to join the deep-seated vessels. From the back of the leg and thigh they receive an accession to their numbers of several vessels; the most of these reach them from the inside, but some few from the outside of the limb. They ultimately terminate in the superficial cluster of glands in the groin. Some few, however, may dip down to join the deep-seated glands and to unite with the deep-seated lymphatics. One may occasionally be seen to pass the inguinal glands to reach those accompanying the external iliac artery.

The inguinal glands also receive the super-

ficial lymphatics from the genitals, from the lower half of the anterior and posterior part of the trunk, from the perineal and gluteal regions. The lymphatics of the scrotum collect into one or two branches, which take their course with the superficial pudic veins to reach the glands in the groin. Those of the penis commencing on the glans and prepuce proceed generally in three principal branches on the body of the organ, two of which are situated laterally, and the third on the centre of its dorsal surface. These three vessels not unfrequently unite near the root of the penis into one vessel, which immediately divides right and left into branches, which also accompany the superficial pudic veins to the inguinal glands. In the direction of the superficial epigastric and circumflexa ilii veins there are several lymphatics derived from the anterior and lateral parts of the abdomen, which empty themselves in the inguinal glands. The superficial lymphatics from the perineal and gluteal regions, some from the loins and posterior and upper part of the thigh, stream round the outer part of the limb in the neighbourhood of the trochanter major to terminate in the same glands.

The vasa efferentia of the inguinal glands, three or four in number, are much larger than the vasa inferentia; they receive the contents of all the lymphatics hitherto described, and pass under Poupart's ligament with the femoral artery and vein to become the vasa inferentia of the glands associated with the external iliac artery. From the anterior and lateral muscular paries of the abdomen, the lymphatics accompany the epigastric and circumflexa ilii arteries, and terminate in the external iliac glands. The external iliac glands are also joined by the vasa efferentia from the glands accompanying the internal iliac artery. These latter receive the lymphatics, associated with the gluteal, ischiatic, and obturatrix arteries, which enter the pelvis by the same openings as the arteries which they accompany. The lymphatics from the prostate gland and vesiculæ seminales, from the bladder and rectum, from the vagina and uterus, those accompanying the internal pudic vessels derived from the interior of the penis and clitoris, and those from the walls of the pelvis, all terminate in the internal iliac glands.

The glands accompanying the common iliac artery, on the one hand, receive their efferent vessels from the internal and external iliac glands, and on the other give their efferent vessels to those, associated with the aorta, which constitute the lumbar glands.

The lymphatics of the testicle, of the kidneys, and renal capsules, those accompanying the lumbar arteries, the lymphatics of the rectum, sigmoid flexure and descending portion of the colon, all terminate in the lumbar glands. Those from the testicle are derived from the interior as well as from the surface of the organ; they take their course upwards with the spermatic arteries and veins in several branches, to reach the renal and lumbar glands.

The lymphatics of the kidneys emerge from its substance at the fissure of the organ, having taken their course with its bloodvessels, where they are joined by the superficial vessels; they pass through the small renal glands, and ultimately reach the lumbar glands.

The lymphatics of the renal capsules unite chiefly with those of the kidneys, but also on the left side with those of the spleen, and on the right with those of the liver. They are at length conducted to the lumbar glands. The lymphatics accompanying the lumbar arteries receive their branches from the structures supplied by those arteries, and empty themselves into the lumbar glands. The lymphatics from the descending colon, from its sigmoid flexure, and from the rectum, take somewhat the course of the inferior mesenteric artery and its branches; they pass through their appropriate glands, and are ultimately received by the lumbar glands.

The vasa efferentia of the lumbar glands cannot be said to receive the contents of all the vessels and glands hitherto described; they, in fact, empty themselves into the principal lymphatics by whose union the thoracic duct is formed, or into the duct itself soon after its formation. The principal lymphatics above alluded to may be traced more or less distinctly from Poupart's ligament to the second lumbar vertebra, where they usually unite to form the thoracic duct, the vessels of opposite sides communicating freely with each other.

Their position and arrangement will be well understood by the accompanying wood-cut.

Fig. 56.

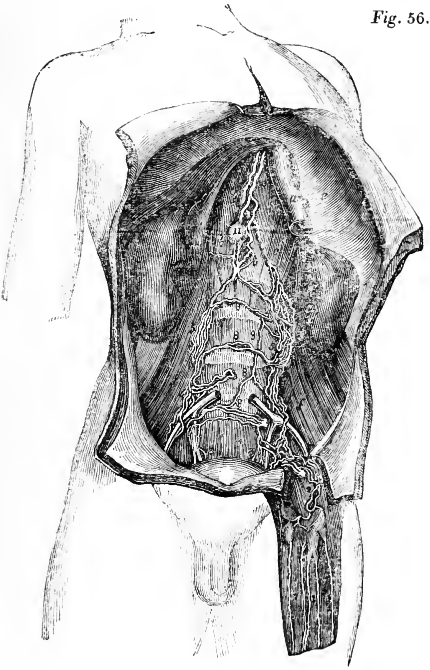

Fig. 56. *Shewing the principal lymphatic branches of the inguinal, iliac, and lumbar regions, into which the vasa efferentia of the glands of these regions empty themselves, and by the convergence and union of which the thoracic duct is generally formed on the body of the second lumbar vertebra. Shewing also in this instance an abrupt globular dilatation in the position of the receptaculum chyli, and a double thoracic duct.—(From a dissection.)*

5, Those accompanying the lumbar glands.
6, The convergence of the vessels of opposite sides.
7 and 10, The trunks from the left and right sides, which in this instance did not unite (as is usually the case) to form the thoracic duct, but passed separately into the cavity of the thorax.
8, Transverse communications between the vessels of opposite sides.
9, A communication between the transverse branches in the vertical direction.
11, The receptaculum chyli, in this instance remarkably abrupt, and of a globular form.

In the dissection from which this wood-cut was taken, the injection did not pass freely into the glands, from which circumstance the vessels are more distinctly seen, as it permitted the glands which partly concealed them to be removed without causing extravasation. These vessels, after taking somewhat the course of the external, internal, and common iliac arteries, may be seen to ascend pretty close to the inner edges of the psoæ muscles, to communicate freely by cross branches, and opposite to about the third lumbar vertebra to pass inwards, on the right side behind the cava, on the left behind the aorta to unite into one vessel on the body of the second lumbar vertebra, behind the root of the right renal artery, and thus to form the commencement of the thoracic duct. In the subject from which the drawing was taken the branches did not unite in the abdominal cavity. Two nearly equal-sized vessels ascended into the thorax, which, however, soon coalesced. The union generally takes place opposite the abrupt dilatation marked No. 11, and which would be termed the receptaculum chyli, although the lacteals generally enter above this point.

The lacteals, properly so called, take origin from the small intestines. During the process of digestion they contain a white fluid, the chyle, but at other times their contents are colourless like those of the rest of the lymphatic system; they are joined by the lymphatics of the caput coli, the ascending and transverse colon; they also communicate with the lymphatics of the liver, spleen, pancreas, and stomach. The more modern opinion is, that the lacteals commence from the villi and from the spaces between the villi in the small intestines, not by open mouths, but by a delicate network of vessels, through the coats of which the chyle is supposed to enter by imbibition. This incipient net-work of lacteals terminates at the roots of the villi in branches, which perforate the muscular coats of the intestines, the trunks of which may be easily distinguished under the serous coat, taking a transverse course to gain the cellular interval between the layers of the mesentery. These are what may be termed the deep-seated lymphatics of the intestines which alone contain the chyle, but there are superficial lymphatics belonging to the intestines situated immediately under the peritoneal coat, which take a longitudinal course and join the deep-seated vessels. From the intestine the principal branches pass in nearly straight lines between the layers of the mesentery, where they traverse the mesenteric glands to accumulate from every portion of the small intestine around the trunk of the superior mesenteric artery. The lymphatics from the cœcum, the ascending and transverse colon, which have passed through their appropriate glands and have accompanied more or less the ilio-colic and colic arteries between the layers of the meso-colon, now join the lacteal vessels. The vasa efferentia from the mesenteric glands form two or more trunks, which, conducted by the root of the superior mesenteric artery, reach the thoracic duct, into which they empty their contents just above its commencement.

The lymphatics of the stomach chiefly accompany the bloodvessels. Those associated with the vasa brevia and with the left gastro-epiploic vessels, having passed through their glands unite with the lymphatics from the spleen. Those accompanying the right gastro-epiploic vessels having traversed their glands communicate behind the pyloric extremity of the stomach and at the commencement of the duodenum, with the lacteals, and with the lymphatics from the liver. At the upper curvature of the stomach, the lymphatics take their course from the cardiac to the pyloric orifice accompanying the branches of the coronaria ventriculi arteries, they pass through the glands there situated, and join the lymphatics descending from the liver in the capsule of Glisson.

The lymphatics of the pancreas near the head of the organ communicate with the lacteal vessels from the duodenum; the rest empty themselves into the lymphatics coming from the spleen.

At the hilum of the spleen the deep-seated lymphatics which have accompanied the bloodvessels in the substance of the organ are joined by the superficial vessels. The principal branches having in their course received lymphatics from the stomach and pancreas, and having traversed the splenic glands, accompany the trunks of the splenic artery and vein, and unite with the lymphatics of the liver in their course to the thoracic duct.

The deep-seated lymphatics of the liver accompany the ramifications of the portal vessels throughout the substance of the organ; they emerge with the hepatic ducts at the transverse fissure of the liver, where they are joined by the lymphatics of the gall-bladder and by the superficial lymphatics from the under surface of the liver. They pass through the glands situated in the capsule of Glisson, receive free communications from the splenic and gastric lymphatics, and ultimately terminate in the thoracic duct either separately or in conjunction with the lacteal trunks.

The superficial lymphatics of the upper surface of the liver form three or four fasciculi, which enter the thorax without joining the trunks of the deep-seated vessels. One set streams from the upper surface of the right, another from that of the left lobe to gain the suspensory ligament of the liver, between the folds of which the larger branches, six or eight in number, pass upwards and enter the thorax between the attachment of the diaphragm and the ensiform cartilage to gain the anterior mediastinum, where they join the large lymphatic vessels accompanying the arteriæ mammariæ internæ. From the right and left lobes in the neighbourhood of the lateral ligaments, and chiefly, though not entirely, from the upper surface of the organ, two other streams of superficial lymphatics tend towards the lateral ligaments, between the layers of which the principal branches pass. They perforate the diaphragm to gain its upper surface, some of them passing backwards to reach the thoracic duct in the posterior mediastinum, while others form a large vessel which creeps upon the thoracic surface of the diaphragm under the pleura and near the margin of the ribs, to gain the anterior mediastinum, where on each side it unites and terminates with those vessels which have arrived at the same point from between the folds of the suspensory ligament. The lymphatics of the left lateral ligament often, however, pass downwards to the abdominal cavity, joining the lymphatics of the under surface of the liver or of the cardiac extremity of the stomach.

The thoracic duct receives but four branches during its passage through the thorax; the lymphatics of the lungs and of the heart, as well as the large branches accompanying the mammariæ internæ vessels, make their exit from the thoracic cavity, to empty themselves into the two lymphatic trunks in the cervical region. The intercostal lymphatics accompanying the intercostal bloodvessels, traverse the little glands situated near the necks of the ribs, take their course to and enter the larger glands in the posterior mediastinum. These same glands also receive the œsophageal lymphatics, and even some communications from the bronchial glands; their vasa efferentia, four or five in number, enter the thoracic duct at different levels.

The large lymphatics accompanying the mammariæ internæ arteries collect their branches from various sources; those from the liver have been already noticed; some pass through the intercostal spaces close to the edges of the sternum: some have accompanied the intercostal branches of the mammariæ internæ vessels; others are received from the thymus gland and pericardium and pleura. The greater part of these vessels pass through the little glands situated in the anterior mediastinum before they are received into the principal branches. These latter pass upwards in front of the transverse vein, to empty themselves on the left side into the termination of the thoracic duct; on the right, into the right lymphatic trunk, or they join the large veins separately, close to the entrance of the two trunks of the system.

The lymphatics of the lungs are of large size, and are divided, as in other parts of the body, into a superficial and deep-seated set. The latter accompany the ramifications of the bloodvessels and air-tubes throughout the texture of the organ, and communicate at various points with the superficial vessels. The principal branches escape from the lung at its root, where they are joined by the superficial vessels, and pass with them through the large bronchial glands. The superficial lymphatics of the lung are larger than those of any other viscus; they are situated in the interlobular fissures immediately under the pleura, and are injected with greater facility than the lymphatics of other parts of the body; their principal branches pass from the surface of the lung towards the inner edge and root of the organ, where they unite with the deep-seated vessels, and pass with them through the bronchial glands. The vasa efferentia of these glands having communicated with the glands in the posterior mediastinum pass upwards on the trachea, where they meet with other glands with which they interchange branches; having entered the cervical region with the trachea, they unite freely with other lymphatics, especially with those of the thyroid gland, and ultimately terminate, on the left side, in the thoracic duct; on the right, in the right lymphatic trunk, or separately in the large veins.

The lymphatics of the heart are neither large nor numerous; they proceed both from the substance and from the surface of the organ accompanying the principal bloodvessels; their appropriate glands are chiefly situated on the ascending thoracic aorta and trunk of the pulmonary artery; where these vessels are covered by the pericardium, they ascend in front of the arch of the aorta, pass between the sternum and transverse veins, communicate freely with the large vessels of the anterior mediastinum, and terminate with them on either side in the trunks of the system, the greater number, however, passing on the left sides to the thoracic duct.

The deep-seated lymphatics of the upper extremity successively accompany the digital arteries, the superficial and deep palmar arches, the radial, ulnar, and interosseous arteries. At least two lymphatic vessels accompany each artery; they communicate by short transverse branches with each other, and also at different points with the superficial lymphatics. At the bend of the elbows they unite into three or four vessels which pass up the arch with the brachial artery to gain the axillary glands, into which they empty themselves. The small glands which not unfrequently may be found accompanying the brachial artery, and even, but more rarely, the ulnar or radial vessels do not generally intercept the deep lymphatic vessels, but the latter rather receive the efferent vessels from these glands, they having collected their afferent vessels from the surrounding textures.

a, a, Commencing lymphatic vessels which accompany the branches of the cephalic and basilic veins.
b, Lymphatic vessels passing from the posterior to the anterior surface of the forearm over its inner edge, with branches of the basilic vein.
d, Lymphatic vessels passing from the posterior to the anterior surface of the forearm over its outer edge, with branches of the cephalic vein.
c, Lymphatic vessels passing from the posterior to the anterior surface of the arm over its inner edge.

The superficial lymphatics of the upper extremity in their passage to the axillary glands follow more or less the course of the subcutaneous veins. Those which accompany the cephalic and basilic veins commence on the dorsal surface of the fingers, where they communicate with the digital lymphatics; from thence they proceed over the metacarpus to the posterior surface of the forearm, tending with their accompanying veins towards its ulnar and radial edges, over which, sooner or later, they pass to gain the anterior surface, and at the bend of the elbow they have all collected in the neighbourhood of the internal condyle. The lymphatics accompanying the median vein take origin from the palmar surface of the fingers, where they communicate with the digital lymphatics; they take their course upwards first on the palm of the hand, then on the anterior surface of the forearm, and at the bend of the elbow join those already traced to the same point. The great majority of these vessels now continue their course upwards over the internal condyle to the inner side of the arm, some of them traversing the little gland or glands situated just above the internal condyle; from thence they take the nearest route to gain the axillary glands, of which they form the principal vasa inferentia. Some three or four of the lymphatics, which in the forearm were associated with the branches of the cephalic vein as far as the bend of the elbow, separate themselves from the rest, and ascend with this accompanying vein on the outer side of the biceps, and in the interval between the deltoid and pectoralis major muscles, where they meet with a gland which they traverse and ultimately pass with the vein over the pectoralis minor muscle to gain the deep-seated lymphatics accompanying the axillary artery.

The axillary glands collect their vasa inferentia also from the upper half of the anterior, posterior, and lateral surfaces of the trunk. From the anterior surface those on the abdomen above the umbilicus ascend; those on the upper part of the chest, joined by some from the cervical region, descend; those on a level with the axilla from the pectoral muscles and the glands of the breast take a transverse direction—all in short converging towards the axilla, where the glands in which they terminate are situated. From the posterior surface of the trunk in a similar way they concentrate from the lumbar, cervical, and dorsal regions to pass over the posterior border of the axilla to reach the same glands.

The vasa efferentia of the axillary glands, four or five only in number, but of large size, receive the lymph conveyed to these glands from the various sources just described; they pass associated with the axillary vessels under the subclavius muscle, unite into one or two branches, which usually pass over the subclavian vein, to terminate either separately in this vein, close to its union with the internal jugular, or else join the lymphatic trunks.

The lymphatics of the head and face may be divided as in other parts of the body into the superficial and the deep-seated. They all have to pass through the glands situated in the cervical region. The superficial accompany principally the veins of the head and face. Those from the head form two groups: one anterior associated with the temporal veins, descends in front of the ear, joins the small glands situated at the root of the zygoma, and in the substance of the parotid gland; it passes with the temporal vein through that gland and below the angle of the jaw continues to follow the course of the vein over the digastric and stylo-hyoid muscles, where it meets with lymphatic glands which it enters; the posterior group accompanies the occipital and posterior auricular veins, traverses the glands behind the mastoid process, and afterwards those situated at the back and upper part of the neck. The facial lymphatics, like the facial veins, receive branches from the forehead and eyelids, pass from the inner canthus of the eye along the side of the nose and over the buccinator muscle, where they meet with one or two small glands; they then gain the anterior edge of the masseter, from whence they pass below the margin of the jaw, to traverse the glands there situated. These three groups of vessels communicate freely with each other in the cervical glands, and are joined by some of the deep-seated lymphatics. These latter may be divided into those of the cranium and those of the face; the former as well as the lymphatics of the interior of the orbit are not sufficiently known to admit of our stating the exact course which they take. Fohmann and Mascagni both conceive that they have discovered the lymphatics of the brain and its membranes and have had them delineated in their published plates; but they differ so materially from each other, and their descriptions are so far from satisfactory that we must be content to say that we are ignorant not only of the course they take but even of their existence. Fohmann represents them to be very large and numerous, situated principally between the arachnoid membrane and pia mater, while Mascagni figures them on the pia mater as exceedingly small and as accompanying some of the veins; others are also depicted as associated with the meningeal vessels; the trunks of these vessels are supposed to descend with the carotid, vertebral, and meningeal arteries and with the internal jugular veins; while Fohmann throws out a hint that they may terminate in the venous system within the cranium.

The deep-seated lymphatics of the face are associated with the bloodvessels; those accompanying the internal maxillary arteries enter the gland or glands in the substance of the parotid, and join the temporal lymphatics. The rest accompanying their bloodvessels reach the upper cervical glands, and communicate freely with the superficial lymphatics already traced to the same glands; the further progress of the lymphatics in the neck is regulated by the position of the glands, which it will be remembered form two groups, one situated between the sterno-mastoid muscle and the trachea, and associated more with the internal jugular vein, the other located in the cellular interval between the sterno-mastoid and trapezius muscles in the neighbourhood of the external jugular. The former receives the lymphatics from the tongue, pharynx, and larynx, and lower down from the thyroid gland, trachea, and œsophagus; while the latter collects them from the muscles of the posterior region of the neck and of the shoulder. The afferent and efferent vessels of these two series of glands have frequent communications with each other. At the root of the neck they unite freely with the lymphatics emerging from the chest and with those of the upper extremities, until ultimately one large vessel is formed on either side, which receives the contents of the whole, and which terminates either by opening separately into the internal jugular vein close to the entrance of the lymphatic trunk, or into that trunk itself.

(S. Lane.)

LYMPHATIC SYSTEM, ABNORMAL ANATOMY.—The congenital variations from the normal distribution of the lymphatic system which have naturally most attracted attention are those of the thoracic duct, or of the right lymphatic trunk; the remainder of the system lying too minute for general investigation, and the mode of its examination being within the scope of only a few.

The thoracic duct frequently varies as to the precise point at which it opens into the venous system, sometimes opening into the subclavian vein, at others into the jugular. A very striking departure of it from its usual arrangement is when it is found opening into the veins on the right side, just as it ordinarily does on the left. I saw an instance of this during the winter of 1834, in the body of a child dissected by Mr. Skey. The duct followed its usual course as high as the fifth dorsal vertebra; it then inclined to the right side, and opened into the angle between the right jugular and subclavian veins. It was remarkable that in this subject the right subclavian artery was abnormal in its mode of origin; it arose from the extreme left portion of the arch of the aorta, and passed to its destination behind the trachea and œsophagus. A similar transposition of the thoracic duct occurs in cases of general transposition of the viscera.

The thoracic ducts have been found sometimes both terminating on the same side, sometimes on opposite sides. It has also been found dividing into two large trunks which pass upwards parallel to each other for a considerable distance, and then unite again. Varieties have been observed as regards its mode of opening into the jugular and subclavian veins. Instead of terminating as a single trunk, it has been found to subdivide into two or three branches, which open separately into the subclavian or jugular veins. At its termination the duct experiences generally some degree of dilatation—in some instances I have seen this so considerable as to have the appearance of an aneurismal enlargement. The duct has likewise been found to empty itself into the vena azygos. In the pig, according to Panizza, a communication between the duct and this vein is constant and normal.

The varieties in the course and distribution of the lymphatic vessels and in the number and position of the glands are doubtless as numerous as those of the veins.

The diseased states of this system may be examined, first, as regards the lymphatic and lacteal vessels; secondly, with reference to the absorbent glands; and, thirdly, with respect to the nature of the contents of the system

Inflammation of the absorbent vessels has long been known to practical men. A number of red lines appearing through the skin, and giving to the touch the sensation of round and hard cords immediately underneath the skin, taking the direction and occupying the position of the superficial lymphatics, are seen to proceed from some point of irritation, as a poisoned wound or a syphilitic sore, towards the nearest set of absorbent glands. There are much tenderness and pain on the least pressure in the whole course of these lines, and the glands to which they go are more or less swollen, and the skin over them is of a reddish colour. These lines correspond to the inflamed absorbents, which, at first isolated, soon excite inflammation in the surrounding cellular tissue, and the hard cords above described are lost in the thickened and infiltrated subcutaneous tissue. When an incision is made into such an inflamed surface, the lymphatics, according to Gendrin, are seen upon the margins of the incision as red fibres, having the irregular, knotted appearance which those vessels exhibit when injected with mercury and converging towards the inflamed tissue of a gland.

It may be fairly presumed that the anatomical characters of these vessels in a state of inflammation are the same as those of the inflamed thoracic duct, examples of which have occurred to Gendrin and Andral. The vessels of its coats (*vasa vasorum*) are much injected, and the coats themselves thickened and rendered friable—the inner coat red, soft, and swollen—sometimes with lymph poured out upon it, which tends to obstruct and obliterate the canal, giving rise to dilatation below the obstructed point, or with pus effused, which also occasions the vessels to be dilated. Sir A. Cooper found adhesion and ulceration of the valves of the thoracic duct in a body in which he could not succeed in injecting that vessel.

In the body of a phthisical patient Andral found the lacteal vessels on the surface of the intestine, corresponding to the situation of an ulceration of the mucous membrane, remarkably white and hard, and so dilated at intervals as to resemble a string of rounded nodules. On examination these nodules were found to be caused by thickening of the coats of the lacteal vessels.

Irregular dilatations or varicosities of the absorbent vessels, but especially of the thoracic duct, have been very frequently observed. These most frequently arise from some pressure impeding the circulation of the fluid in them, as a tumour or aneurism pressing on the thoracic duct in some part of its course. Mr. Cruikshank delineates a thoracic duct, remarkable for its great size. It was found in a man 40 years of age, but the cause of the dilatation was not apparent, as no obstruction existed either at the entrance of the vessel into the veins or in any part of its course. The great trunks of the absorbents accompanying the large arteries in the extremities were enlarged also, but the cutaneous absorbents were of their usual size. The case referred to by Dr. Baillie, in which the duct is said to be as large as the vena azygos, is probably the same.

The morbid changes of the absorbent glands are much more familiar to us than those of the lymphatics themselves, as being more appreciable if not of more frequent occurrence. Inflammatory states of these bodies are very often met with, either in conjunction with inflamed lymphatic vessels or alone. In inflammation the absorbent glands become enlarged, very vascular, and painful to the touch, and the surrounding cellular tissue participates in the inflammation, so that if several glands be inflamed a tumour of some size and hardness will be formed. The tissue of the absorbent glands themselves is not prone to run into suppuration, but pus will often speedily form in the surrounding and connecting cellular tissue, which by-and-bye accumulates, forms an abscess, is discharged, and leaves the glands, with the intervening cellular tissue, dissected away by the suppurative and sloughing process. It is thus that a bubo will originate from one or more inflamed inguinal or axillary glands, and when the constitution is enfeebled and favourable to a phagedenic action, we frequently find these glands exposed by the destruction of the skin and cellular tissue. Sometimes, however, little collections of pus form in the glands themselves, and, according to Gendrin, the fluid in the glands differs remarkably from that in the cellular tissue, the latter being thick, opaque, viscid, and of a greenish hue, whilst the former is clear, transparent, and almost colourless. Gendrin infers from his observations that the lymphatics which permeate the inflamed glands become obliterated; but Dr. Bocher, a German anatomist, quoted by Andral, affirms that he repeatedly injected with mercury lymphatic ganglions presenting different forms of morbid alteration, and that he invariably found the injection pass freely through all the convolutions of vessels, whence he concludes that in diseases of these ganglions the lesion is, at least in the great majority of cases, confined to the cellular tissue that unites the convolutions of the vessels, or to the coats of the vessels, but that there is no obstruction of their cavity. The lymphatic glands are also liable to be chronically inflamed, or to be hypertrophied, and under both conditions put on the same anatomical characters, viz. redness, increased size, induration. In children, of both sexes, the glands at the angle of the jaw and those of the neck frequently afford examples of these morbid states. The bronchial and mesenteric glands likewise present similar enlargements. Atrophy of the absorbents occurs very commonly in old persons.

Various deposits are met with in the absorbent glands. Of these the most frequent is tubercle, or a cheesy curdy matter of a yellowish hue, which bears much resemblance to tubercle. This matter is deposited in isolated spots in the glands, or else appears to be infiltrated throughout their substance. In phthisical subjects, in scrofulous patients, these deposits are usually met with. The cervical, bronchial, and mesenteric glands are those most frequently affected, but all the absorbent glands are very often engaged. Louis states that in phthisis* the relative frequency of tuberculization of these glands is as follows,—the mesenteric, meso-cœcal, meso-colic, cervical, lumbar, and axillary glands, and that the bronchial glands are as often affected as the mesenteric.

The glands affected in children observe pretty nearly the same order as regards the relative frequency of the affection. They are always much enlarged, and frequently closely adherent to each other or neighbouring textures; and the cheesy matter either infiltrates the tissue or is deposited in small portions in the glands. In an infant, which I had lately under my care in conjunction witn Mr. Holt, it was found, upon post-mortem inspection, that the severe cough with remittent dyspnœa, under which the child sunk, was owing to a mass of enlarged bronchial glands, of the size of a hen's egg, filled with cheesy matter, pressing on the primary bronchi and on the pulmonary plexus of nerves.

Cancer, melanosis, and encephaloid matter are frequently found in these bodies, especially when other organs have been similarly affected. Deposits of calcareous matter are likewise often met with in them, and, as far as my experience goes, in none more frequently than in the bronchial glands; these deposits occur generally in old subjects; they consist of phosphate of lime. It has been suggested that this calcareous phosphate might be derived from the earthy matter of the bones; and Andral relates two remarkable cases in which there was a coincidence between the deficiency of a certain quantity of osseous matter where it should naturally be deposited and its deposition in the lymphatic system. In one, a boy æt. 16, the bronchial, mesenteric, and pelvic glands were occupied by calcareous concretions, and his lungs also contained them; there was also an abscess in one of the iliac fossæ, with erosion and destruction of the os ilii. In a second case, a woman, æt. 33, who died of acute pleuritis, supervening upon a chronic pulmonary affection, the bodies of six vertebræ, the last dorsal and five lumbar, were found destroyed, and calcareous concretions were found in the cervical, thoracic, bronchial, abdominal, pelvic, axillary, and inguinal glands.

The black matter which is so often found in the bronchial glands must not be confounded with melanoid matter. We seldom examine a body that has passed adult age without finding more or less of this matter in the bronchial glands, derived doubtless from the pulmonary black matter, which is conveyed to these glands by the pulmonary lymphatics.

The changes which occur in the lymph itself have not as yet received any attention from pathologists. This fluid is, however, occasionally either mixed with or replaced by others in the lymphatic vessels. Cases are on record (Majendie, Dupuytren) in which it is stated that the lymphatics in the neighbourhood of sanguineous effusions into the pleura and peritoneum have been filled with blood, and that pus had been absorbed into them from a neighbouring abscess. Such cases require confirmation with our present improved means of observation, as it is difficult to understand how particles so large as the blood corpuscles, or the globules of pus, could have permeated the coats of the absorbent vessels. In future the microscope must be brought to our aid in the examination of such cases. Authors relate likewise that bile has been found in the lymphatics of the liver and in its neighbourhood, in cases where the flow of that fluid has been obstructed, (Mascagni, Saunders;) and Tiedemann states that in dogs, in which he had tied the hepatic duct, the biliary secretion likewise made its way into the lymphatics. Earthy matter, as in the glands, has also been found in the vessels themselves, and the tubercular, encephaloid, or cancerous matter has likewise been met with stopping up these vessels.

(R. B. Todd.)

MAMMALIA.—(Lat. *Mamma*, a teat; Ger. *Saügethiere;* Fr. *Mammifères;* Eng. *Mammals*.)—The most highly organized class of animals, distinguished outwardly by a total or partial covering of hair, and generally by having external teats or mammæ, whence the name. Mammals always possess mammary glands, and suckle their young; the fœtus is developed in the womb; their leading anatomical character is to have lungs composed of a highly vascular and minutely cellular structure throughout, and suspended freely in a thoracic cavity, separated by a muscular and tendinous septum or diaphragm from the abdomen.

Mammals, like birds, have a heart composed of two ventricles and two auricles: they respire quickly, and have warm blood; inspiration is performed chiefly by the agency of the diaphragm: the right auriculo-ventricular valve is membranous, at least never entirely fleshy; and the aorta bends over the left, never over the right bronchial tube. The primary branches of the aorta are given off, not immediately after, but at a little distance from its origin, and there is less constancy in the order of their origin than in birds: the phrenic arteries, the cœliac axis, and the superior mesenteric artery are always branches of the abdominal aorta, which terminates by dividing beyond the kidneys into the iliac arteries, from which spring both the femoral and ischiadic branches. The caudal or sacro-median artery, which in some long-tailed Mammals assumes the character of the continued trunk of the aorta, never distributes arteries to the kidneys or legs, as in birds. The kidneys are nourished, and derive the material of their secretion, exclusively from the arterial system: their veins are simple, commencing by minute capillaries in the parenchyma, and terminating generally by a single trunk on each side, in the abdominal vena cava: they never anastomose with the mesenteric veins.

The kidneys are relatively smaller, and present a more compact figure than in the other vertebrate classes; their parenchyma is divided into a cortical and medullary portion, and the secerning tubuli terminate in a dilatation of the excretory duct called the pelvis. The tubuli uriniferi are slightly branched, and the ramification takes place in the dichotomous, and not pinnatifid manner: they are convoluted in the cortical, and straight in the medullary portions of the kidney, and with a few exceptions terminate upon valvular prominences, called mammillæ. The ureters convey the urine to a urinary bladder situated anterior to the rectum, and to the genital tubes or cavities. The liver is generally divided into a greater number of lobes than in birds. The portal system is formed by veins derived exclusively from the spleen and chylopoietic viscera. The cystic duct, when it exists, always joins the hepatic, and does not enter the duodenum separately. The pancreatic duct is commonly single.

The mouth is closed by soft flexible muscular lips. The upper jaw is composed of palatine, maxillary, and intermaxillary bones, and is fixed; the lower jaw consists of two rami, which are simple, or formed by one bony piece, and are articulated by a convex or flat condyle to the base of the zygomatic process, and not to the tympanic element of the temporal bone; the base of the coronoid process generally extends along the space between the condyloid and the alveolar processes. The jaws of Mammals, with few exceptions, are provided with teeth, which are arranged in a single row; they are always lodged in sockets, and never anchylosed with the substance of the jaw; in most cases they present different forms in the same individual, and the molars have two or more fangs. Never more than two teeth succeed each other in the vertical direction, and in this case the fang of the deciduous tooth is always completed before it is shed. The tongue is fleshy, well developed, with the apex more or less free. The posterior nares are protected by a soft palate, and the larynx by an epiglottis; the rings of the trachea are generally cartilaginous and incomplete behind: there is no inferior larynx. The œsophagus is continued without partial dilatations to the stomach, which varies in its structure according to the nature of the food, or the quantity of nutriment to be extracted therefrom. An epiploon of greater or less extent is continued from the great curvature of the stomach. The termination of the duodenum is generally tied closely to the spine, above the root of the mesentery. The colon is suspended generally by a distinct duplicature of peritoneum, called the meso-colon: the *cæcum coli* when present is usually single. The rectum commonly terminates by an aperture distinct from that of the urinary or genital canals.

The female generative organs consist of two ovaries, which with very few exceptions are equally developed; there are always two oviducts or Fallopian tubes, a simple or more or less completely bifid uterus, a vagina, which is commonly single, and a clitoris. The essential element of the ovum, the germinal vesicle, acquires a surrounding granular stratum (tunica granulosa), a small vitelline mass, and a vitelline membrane, before it quits the ovisac. The ovisacs or Graafian vesicles, consisting of an ovarian vesicle and a vascular layer of the condensed cellular tissue, or stroma of the ovary, are never pendent, and rarely racemose.

The male organs consist of two equally developed testes, commonly situated in an external tegumentary pouch or scrotum: the vasa deferentia form an epididymis at their commencement, and frequently communicate with the ducts of vesiculæ seminales at their termination, and the semen is conveyed outwardly along a complete urethral canal, where it is mingled with the secretion of certain accessory glands, of which those called "Cowperian," or "preprostatic," are constant; there are also generally prostatic and in many cases vesicular glands. The penis is always perforated by an urethral canal, along which, with very few exceptions, the urine as well as the semen is conducted from the body.

The true vertebræ of Mammalia have their bodies ossified from three centres, and present for a longer or shorter period of life a compressed epiphysis at each extremity. They are articulated by concentric ligaments with interposed glairy fluid, forming what are called the intervertebral substances; the articulating surfaces are generally flattened, but sometimes, as in the neck of certain Ruminants, they are concave at one end and convex at the other; such a vertebra, however, may be distinguished from a vertebra of a Reptile, with a similar ball-and-socket structure of the articular surfaces, even when found in a fossil state, and when the test of the articulating medium cannot be applied, by the constant anchylosis or confluence of the annular with the central part or body. The cervical vertebræ, with one or two exceptions, are seven in number, neither more nor less; the Monotremes, which are the instances commonly opposed to other generalizations, form no exception to this rule. The lumbar vertebræ are more constant and more numerous than in other classes of vertebrate animals. The atlas is articulated by concave articular processes to two convex condyles, which are developed from the ex-occipital elements of the last cranial vertebra. The tympanic element of the temporal bone is restricted in function to a subserviency to the organ of hearing, and never enters into the articulation of the lower jaw. The frontal bones are developed each from a single centre; there are no anterior or posterior frontals. The olfactory nerves escape from the cranial cavity through numerous foramina of a cribriform plate. The optic foramina are always distinct from one another, and generally from the fissuræ laceræ anteriores, and consequently give passage only to the optic nerves and ophthalmic arteries. The carotid canals do not intercommunicate. The cranial bones, in regard to the number and persistency of their sutures, are intermediate in character to those of Birds and Reptiles. The anterior extremity of the skull is always formed by both the upper and lower jaws. The scapula is generally an expanded plate of bone; the coracoid, with two exceptions, appears as a small process of the scapula: the clavicle is inconstant as to its presence; the sternum consists of a narrow and usually simple series of bones; the sternal portions of the ribs are generally cartilaginous, and fixed to the vertebral portions without the interposition of a distinct articulation; there are no abdominal ribs or abdominal sternum. The pubic and ischial arches are generally complete, and united together by bony confluence on the sternal aspect, so that the interspace of the two bony pelvic arches is converted into two holes, called *foramina obturatoria*, or *thyroidea*.

The brain in Mammalia consists of cerebral and optic lobes, cerebellum and medulla oblongata, but the optic lobes are placed on the upper part of the crura cerebri, are solid, are always divided by a transverse fissure, and are generally concealed by the cerebral lobes, in consequence of the large relative size of these masses; the decussation of the corpora pyramidalia is always distinctly marked: the tuber annulare and lateral lobes of the cerebellum have a correspondingly conspicuous development; the ventricles of the cerebrum are large, and contain a corpus striatum and cornu ammonis; the fornix is always well developed, but the following aphorisms in Cuvier's celebrated abstract or condensation of M. Serres' prize essay are applicable only to the placental Mammalia, viz. "The corpus callosum as well as the pons Varolii are peculiar to Mammalia. The corpus callosum is developed in direct proportion to the size of the corpora striata and hemispheres. It increases progressively from Rodentia to Man. The corpus collosum is developed in direct proportion to the development of the tuber annulare."

In the Marsupial Order, as in the Kangaroo and Wombat, the cerebral hemispheres are relatively larger and more complicated with convolutions than in any Rodent, yet the transverse commissure which represents the rudiment of the corpus callosum connects only the hippocampi majores; it is not separated from the fornix by any septum lucidum; and, upon divaricating the cerebral hemispheres, the lateral ventricles are as much exposed as when, in placental Mammalia, the corpus callosum has been removed. The tuber annulare, however, exists in the Marsupial as in the Placental Mammalia, and illustrates its correlation with the lateral lobes of the cerebellum. The class Mammalia is the only one in which the cerebral hemispheres are observed to have their vascular superficies multiplied or increased by convolutions, which arrive at their maximum of development in Man.

The olfactory nerves of mammals are soft, and divide into numerous branches in the cranium, which pass out by the orifices of the cribriform plate of the æthmoid.

The nervi vagi principally supply the larynx, form a plexus around the œsophagus, and do not unite into a single trunk before passing to the stomach. The left recurrent nerve, and not the right, bends round the trunk of the aorta.

The cervical portion of the sympathetic nerve passes along the neck on the sternal aspect of the transverse processes of the vertebræ; and its trunk in the thorax and abdomen is not immediately connected with the ganglia of the spinal nerves. The splanchnic nerves form large ganglia before giving off the visceral plexuses.

The sclerotic coat of the eye is a fibrous membrane, and never contains bony plates. In the quantity of aqueous humour and the convexity of the lens, Mammals are generally intermediate to Birds and Fishes; but they have no marsupium or pecten, nor any choroid gland.

The organ of hearing is characterized in Mammalia by the full development of the cochlea with a lamina spiralis; there are three distinct ossicles in the tympanum; the membrana tympani is generally concave externally, and the meatus auditorius externus often commences with a complicated external ear, having a distinct cartilaginous basis.

The external apertures of the organ of smell are provided in Mammalia with moveable cartilages and muscles, and the extent of the internal organ is increased by accessary cavities or sinuses which communicate with the passages including the turbinated bones.

The tongue is always soft and fleshy, and its gustatory surface is provided with conical, fossulate, and fungiform papillæ; it is supplied by a large proportion of the third division of the fifth pair of nerves, as well as by the ninth and glosso-pharyngeal.

Classification.—The Mammalia were first separated from other four-footed animals and distinguished as a class or particular group (genos) by Aristotle, the founder of natural history, by whom they were denominated *Zootoka*, or Viviparous animals. The Greek philosopher divided the *Zootoka*, according to the nature of their locomotive organs, into three sections: 1st, *Dipoda*, or bipeds; 2d, *Tetrapoda*, or quadrupeds; and 3d, *Apoda*, or impeds, which comprehends the Whale-tribe. The second of these primary divisions, —the quadrupeds,—which includes by far the largest proportion of the class, and in common parlance is considered as the class itself, is subdivided by Aristotle into two great natural groups, according to the modifications of the organs of touch. In the first of these groups, the extremities of the digits are left free for the exercise of the tactile sense, the nail or claw being placed on one side only (Unguiculata of Ray); in the second group, the digits are inclosed in hoofs (Ungulata of Ray). For the convenience of treating of the different forms of the Unguiculate quadrupeds, Aristotle employs for their further subdivision another system of organs, viz. the teeth. His first group or family is composed of those Unguiculates which have the front teeth trenchant, or terminating in a cutting edge, and the back teeth triturant, or with a flattened surface, as the Apes (*Pithecoida*) and the Bats (*Dermoptera*): his second family includes the Unguiculate quadrupeds with acuminated, canine, or carnivorous teeth, and is called *Karcharodonta*, or *Gampsonucha*; whilst the quadrupeds corresponding with the Rodent order of modern naturalists are grouped together and indicated by a negative dental character, viz. the absence of canine teeth.

With respect to the hoofed or Ungulate quadrupeds, Aristotle continues to employ the organs of progressive motion for the subordinate characters, and divides them into, 1st, *Polyschidæ*, or multungulates, as the Elephant, &c.; 2d, the *Dischidæ*, or bisulcates, including the Ruminants (*Merykozonta*), and the Hog-tribe; 3d, the *Aschidæ*, or solidungulate quadrupeds, as the Horse and Ass.

The Apodal Zootoka, which form the third of Aristotle's more comprehensive groups, underwent no corresponding subdivision in his system. It embraces the modern Cetacea, under the name of *Ketoda*. Thus the natural class of animals, now universally recognized under the Linnæan epithet Mammalia, although it comprehends creatures the most diverse in their forms and habits, some, e. g. skimming along the air with wings like birds, others habitually dwelling on the ocean disguised as fishes, was clearly appreciated and first indicated by Aristotle, who included therein the Bat and the Whale, with the ordinary hairy quadruped and the naked biped, according to principles acknowledged as consisting with the soundest philosophy by the best-informed physiological naturalists of the present day.

During the two thousand years which have elapsed since Aristotle wrote and lectured on natural history, the ideas of learned men regarding the nature and classification of Mammals received no improvement, and any change which they underwent was for the worse. Our great countryman Ray was the first to introduce any amelioration of Aristotle's arrangement. This arises chiefly from the tabular form in which he expressed his ideas, and in which the subordination of the characters and groups is more definitely set forth than in the existing compendium of Aristotle's History of Animals. Ray's improvements of classification relate, however, only to the Tetrapodous Mammals. It is as follows:—

" *A Table of Viviparous Four-footed Animals.*

" Viviparous hairy animals or quadrupeds are,—

- *Ungulate*, and these either
  - *Solidipedous*, as the HORSE, ASS, ZEBRA.
  - or *Bisulcate*, which are
    - *Ruminants* with horns, that are
      - Persistent, as in the OX, SHEEP, GOAT,
      - or Deciduous, as in the STAG.
    - or *Not Ruminants*, as the HOG.
  - or *Quadrisulcate*, as the RHINOCEROS, HIPPOPOTAMUS.
- or *Unguiculate*, whose feet are either
  - *Bifid*, as in the CAMEL, or
  - *Multifid*, which are
    - With *digits* adhering together, and covered with a common integument, so that the extremities alone are visible at the margin of the foot, and are covered with obtuse nails, as in the ELEPHANT.
    - With *digits* in some measure distinct and separable from each other, the nails being
      - *Depressed*, as in APES,
      - or *Compressed*, where the incisor teeth are
        - *Many*, in which group all the animals are carnivorous and rapacious, or at least insectivorous, or subsist on insects with vegetable matter:
          - *The larger ones* with the
            - *Muzzle short*, and head rounded, as the Feline tribe; or with the
            - *Muzzle long*, as the Canine tribe;
          - or *The smaller ones* with a long slender body, and short extremities, as the Weasel or Vermine* tribe;
        - *Two very large*, of which tribe all the species are phytivorous, as the HARE."

" The anomalous species," Ray afterwards observes, " among the viviparous quadrupeds with a multifid foot are the Hedge-hog, the Armadillo, the Mole, the Shrew, the Tamandua, the Bat, and the Sloth. The first five of these species agree with the *canine* and *vermine*

* Genus *Vermineum*, from their worm-like form.

genera in their elongated muzzle, but differ from them in the form and disposition of the teeth: the Tamandua, indeed, is altogether destitute of teeth: the remaining two anomalous species have the muzzle shortened."

Linnæus defines the Class Mammalia, as follows:—

Heart, with two auricles and two ventricles.

Blood, warm.

Lungs, respiring reciprocally (" *Pulmones respirantes reciproce.*")

Jaws, incumbent, covered; armed with teeth in most.

Penis intrans.

Generation, viviparous; lactiferous.

Senses, tongue, nostrils, eyes, ears, tactile papillæ.

Covering, hairs; few in tropical; very sparing in aquatic mammals.

Support, four feet, except in those which are entirely aquatic, in which the posterior feet are bound together in the fin of the tail. A *tail* in most.

Wih respect to classification, Linnæus, like Aristotle and Ray, founds his primary divisions of the Class Mammalia on locomotive organs; but his secondary divisions or orders are taken chiefly from modifications of the dentary system. The following is the scheme of his arrangement:—

MAMMALIA.	*Unguiculate*	Front teeth, none in either jaw	BRUTA.
		Front teeth, *cutters* 2, laniaries 0.	GLIRES.
		Front teeth, *cutters* 4, laniaries 1.	PRIMATES.
		Front teeth, *piercers* (6, 2, 10), laniaries 1.	FERÆ.
	Ungulate	Front teeth, in both upper and lower jaw	BELLUÆ.
		Front teeth, none in the upper jaw	PECORA.
	Muticate	Teeth variable	CETE.

(From the '*Systema Naturæ*,' ed. xvi. Holmiæ, p. 24.)

On comparing the three preceding systems, it will be found that the most important errors of arrangement have been committed, not by Aristotle, but by the modern naturalists. Both Ray and Linnæus have mistaken the character of the horny parts enveloping the toes of the elephant, which do not defend the upper part merely, as is the case with claws, but embrace the under parts also, forming a complete case or hoof.

With respect to Linnæus, however, it must be observed, that although he has followed Ray in placing the elephant in the unguiculate group of quadrupeds, he has not overlooked the great natural divisions which the latter naturalist adopted from Aristotle, as is evident from the Table above quoted. He erred, perhaps, in not giving names to those primary divisions.

From the manner in which Linnæus has arranged his Orders in this Table, it would seem that he had the circular progression of affinities in view. The Walrus among *Bruta* connects the commencement of the chain with *Cete*, which forms the last link; but whether or not he had perceived the affinity of *Elephas* to the *Glires*, and intended it as a transitional genus to that Order, as Cuvier has subsequently shown it to be, is less certain.

Pallas* divides the Class Mammalia into seven Orders, viz.

I. FERÆ. II. SEMIFERÆ. III. GLIRES. IV. RUMINANTIA. V. ANOMALOPODA. VI. BELLUÆ. VII. CETACEA.

Order I. *FERÆ.*

The FERÆ are characterized by *incisors*, small; *laniaries* very powerful; *molars* trenchant and tricuspid, (*lacero-tricuspidatos*); *clavicles minute* suspended in the flesh, almost obsolete and functionless; *vertebral column* elongated and flexible; *muscular force* immense; *æsophagus* and *alimentary canal* wide, short, with a very short cœcum and colon; *digestive power* so active as to reduce even bones to chyme; *penis* supported by a bone; *prolific virtue* not very great; *young* born blind; *skin* pretty flexible, and *fat* soft, sometimes oily.

The genera included in the Order thus philosophically characterized are

1. *Felis*. 2. *Canis*. 3. *Ursus*. 4. *Meles*. 5. *Viverra*. 6. *Mustela*. 7. *Phoca*.

Order II. *SEMIFERÆ.*

" All preconceived opinion being laid aside, the following genera," says Pallas, " seem to be linked together by an uninterrupted series of affinities and to constitute a strictly natural family, viz. *Simia*, *Lemur*, *Vespertilio*, grouped together by Linnæus under the name of Primates—with these, *Didelphys*, *Talpa*, *Sorex*, and *Erinaceus*, which he classed without any stable character with the *Feræ*. These differ from the Order *Feræ* in the continuity of the dental series, generally also in the number of incisors and in the less elongated canines; in the multifarious and singular structure of the pentadactyle feet, the perfect clavicles, and in short in their habit, food, and general nature."

Order III. *GLIRES.*

" This Order," says Pallas, " is so natural and clear in its characters that it did not escape the older Zoologists. All the genera composing it agree in their bifid or hare-lip, their rosorial incisors generally two in number, their perfect clavicles, sub-bipartite stomach, large cœcum, and great apparatus of the male generative organs, exceeding that of any other order. They produce a blind offspring, as in the *Feræ* and *Semiferæ*." It must be observed, however, that the perfect clavicles and large cœcum are not, as Pallas states, constant characters of the Glires.

* Zoographia Rosso-Asiatica, 1831.

Order IV. *RUMINANTIA.*

The Ruminantia, or the natural Order recognized by Aristotle under the name of Μηρυκάζοντα, subsequently adopted by all Zoologists, have their external and internal characters alike conspicuous and cogent. These, according to Pallas are, *incisors* wanting in the upper jaw; *hoofs* bifid; *habit* of the whole body; *stomach* quadruple; *intestines* very long with a cœcum; *suet* for fat; *cotyledons* in place of placenta. The genera included in this order are *Camelus, Moschus, Cervus, Ægoceros, Bos, Antilope.*

Order V. *ANOMALOPODA.*

The genera grouped together by Pallas under this name differ, he observes, from each other in their dental apparatus and the structure of their feet, yet nevertheless are linked together by natural affinity (" *sed tamen inter se naturali affinitate cohærent*"). Thus *Hippopotamus* is allied to *Equus*, the horse to *Rhinoceros* and its congener *Hydrochærus*, and these to the genus *Sus*. The following characters are common to the whole order: *molares* truncate, triturating; *feet* ungulate, supported on the digits; *stomach* a macerator, with enormous colon and cœcum; *clavicles* wanting; *produce* perfect; *food* vegetable.

The genera which Pallas exemplifies in this Order, which corresponds with the *Pachyderma* of Cuvier (the Proboscidians being excepted), are *Equus, Sus, Rhinoceros, Hippopotamus.*

Order VI. *BELLUÆ.*

In this Order,— characterized by *incisors* none; *canines* projecting from the upper jaw only, composed of ivory; *molars* few; *mammæ* pectoral (in which the Belluæ mainly differ from the *Anomalopoda*); *feet*, with connate digits forming a shapeless sole;—Pallas includes the genera *Elephas* and *Rosmarus*, rejecting therefrom the *Trichecus* or Manatee, as having the hind-feet coalescing with the tail, and therefore more rightly to be referred to the Cetaceous Order. In this latter view Cuvier agrees with Pallas. As to the rest it is scarcely necessary to say that the tusks of the Elephant differ from those of the Walrus in being implanted in the inter-maxillary bones instead of the maxillaries, and are therefore regarded as *incisors.*

Order VII. *CETACEA.*

Pallas observes that since the Cetacea differ from the other *Lactantia* chiefly in having their boneless posterior extremities blended with the cartilaginous tail (" *quod artus posticos exosses, in caudam cartilaginibus fultam coadunatos obtinent*"), the *Manatus* and *Trichechus* rightly fall under this Order, although they approach more to the nature of Quadrupeds. Both the Manatus proper and the *Rytina*, which is the *Manatus Borealis* of Pallas, agree, however, with the true Cetacea in having no other rudiments of posterior extremities than some small pelvic bones.

We shall now proceed to the arrangement of the Mammalia proposed by Cuvier in the last edition (1829) of the '*Règne Animal;*' and this is the more interesting, as, in giving the outline of his method, he developes the principles on which the divisions of the class are founded.

" The characters by which Mammalia differ most essentially one from another are derived from the organs of touch, from which results their degree of dexterity, and from the organs of mastication, which determine the nature of their food; and, as a corollary to these, depends not only every thing which is connected with the digestive functions, but a variety of other circumstances relative even to their degrees of intelligence.

" The perfection of the organs of touch is estimated by the number and mobility of the digits, and the extent to which they are inclosed in a claw or in a hoof. A hoof which completely incloses that part of the digit which touches the ground, precludes the exercise of it as an organ of touch or of prehension. The opposite extreme is where the nail, in the form of a simple lamina, covers only one side of the end of the digit, leaving the other side in possession of all its delicacy of tact.

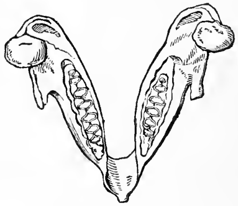
" The kind of food is indicated by the molar teeth, to the form of which the articulation of the jaws invariably corresponds.

" For cutting flesh, the molar teeth must be trenchant and serrated; and the jaws fitted together, so as to move like the blades of a pair of scissors, simply opening and closing in the vertical direction.

" For bruising grains and roots, the molar teeth must have flattened crowns, and the jaws a horizontal motion: and further, that the grinding surface may be always unequal, like a millstone, the teeth must be composed of substances of different degrees of density, and consequently wearing down in different proportions.

" The ungulate quadrupeds are all of necessity herbivorous, or with flat-crowned molars (*fig.* 59), because the conformation of their feet does not permit them to seize living prey.

Fig. 59.



Lower jaw, African Elephant.

" The unguiculate animals are susceptible of more variety. They are not limited to one kind of food; and, besides the consequent variation in the form of their molars, they differ materially from each other in the mobility and sensibility of their digits. There is, moreover, a characteristic which prodigiously in-

fluences their dexterity, and gives variety to their modes of action: it is the faculty of opposing a thumb to the other fingers, so as to seize the smallest objects, which constitutes a *hand*, properly so called. This faculty is carried to its highest degree of perfection in man, in whom the whole anterior extremity is free, and can be exclusively employed in prehension. These different combinations, which strictly determine the nature of the several mammiferous animals, have formed the grounds for their distribution into the following Orders.

" Amongst the Unguiculate animals, the first is MAN, who, in addition to his peculiar privileges in every other respect, is distinguished zoologically by possessing hands on the anterior extremities alone; the posterior extremities being destined to sustain him in the erect position. (*Fig.* 60.)

" The Order which comes nearest to Man, —that termed *Quadrumana*,—has hands on the four extremities. (*Fig.* 61.)

" Another Order, termed *Carnivora*, has not the thumb free and opposable on either the anterior or posterior extremities. (*Fig.* 62.)

" These three Orders possess likewise severally the three kinds of teeth, viz. molars, laniaries, and incisors.

" The quadrupeds of the fourth Order, viz. the *Rodentia*, have the digits differing little from those of the *Carnivora;* but they want the laniary teeth, and have the incisors of a form and disposition altogether peculiar to themselves. (*Fig.* 63.)

" To these succeed the animals whose digits now become much cramped, being sunk deep in large and, most commonly, crooked claws. They are further defective in the absence of incisor teeth; some of them even want the laniaries, and others are altogether destitute of dentary organs. We shall comprehend them under the term *Edentata*. (See *fig.* 33, vol. ii. p. 49.)

" This distribution of unguiculate animals would be perfect, and would form a very regular chain, if New Holland had not lately furnished us with a small collateral chain, composed of the *Marsupial* animals, all the genera of which, while they are connected by a general similarity of organization, at the same time correspond in their dentition* and diet, some to the *Carnivora*, others to the *Rodentia*, and a third tribe to the *Edentata*.

" The Ungulate animals are less numerous, and present fewer variations of form.

" The *Ruminantia*, by their cloven feet, (*fig* 64,) their want of upper incisors, (*fig.* 65,) and their complicated stomach, form a very distinct Order.

" All the other quadrupeds with hoofs might be united into a single Order, which I would call *Pachydermata* or *Jumenta*, (*fig.* 66,) the elephant excepted, which might form an Order of itself, having some remote affinities to the Order *Rodentia*. The Pachyderms have commonly incisors in the upper as well as the lower jaw. (*Fig.* 67.)

" Last of all come the Mammalia which have no hinder extremities, and whose fish-like form and aquatic life would induce us to form them into a separate Class, if their œconomy

* In the article MARSUPIALIA it will be shown how much more essential are the points of resemblance between the dentition of the different Marsupial animals than between any of these and the placental genera, with which they correspond in diet.

was not in every other respect the same as in the Class in which we shall leave them. They are the warm-blooded fishes of the ancients, or the *Cetacea*, which, combining the powers of other Mammalia with the advantage of being sustained upon the watery element, include the most gigantic forms to be found in the whole animal creation."—*Règne Animal*, 2nd edit., p. 65.

Having thus given a brief exposition of the principles which have guided five of the most original writers on Natural History in their primary arrangement of Mammalia, we shall next subjoin a short tabular view of the genera or minor groups included by Linnæus and Cuvier in their respective Orders.

The System of Mammalia of Linnæus, from the 12*th edition of the ' Systema Naturæ.'*

A. Unguiculata.

I. PRIMATES.

Fore teeth cutting; upper ones parallel, four; *laniaries* solitary. *Teats* pectoral, two. *Food*, fruits, except a few which use animal food. 1. HOMO. 2. SIMIA. 3. LEMUR. 4. VESPERTILIO.

II. BRUTA.

Fore teeth none in either jaw. *Feet* with large nails. *Food* mostly vegetables. 5. ELEPHAS. 6. TRICHECUS. 7. BRADYPUS. 8. MYRMECOPHAGA. 9. MANIS. 10. DASYPUS.

III. FERÆ.

Fore teeth conical, usually six in each jaw; *laniaries* long; *molaries* pointed, conical. *Food*, carcasses and living prey. 11. PHOCA. 12. CANIS. 13. FELIS. 14. VIVERRA. 15. MUSTELA. 16. URSUS. 17. DIDELPHIS. 18. TALPA. 19. SOREX. 20. ERINACEUS.

IV. GLIRES.

Front teeth cutting, two in each jaw. *Food*, bark, roots, vegetables, which they erode or gnaw. 21. HYSTRIX. 22. LEPUS. 23. CASTOR. 24. MUS. 25. SCIURUS. 26. NOCTILIO.

B. Ungulata.

V. PECORA.

Fore teeth cutting, many in the lower jaw, none in the upper jaw. *Feet* bisulcate. Four stomachs. *Food*, herbs, which they pluck, and afterwards ruminate. 27. CAMELUS. 28. MOSCHUS. 29. CERVUS. 30. CAPRA. 31. OVIS. 32. BOS.

VI. BELLUÆ.

Fore teeth obtuse. *Tread* heavy. *Food*, vegetables. 33. EQUUS. 34. HIPPOPOTAMUS. 35. SUS. 36. RHINOCEROS.

C. Mutica.

VII. CETE.

Teeth in some horny, in others bony. In place of *Feet* they have pectoral fins without claws; and a horizontal flattened tail. *Nostrils* terminating in one or two fistulous apertures at the anterior and upper part of the head. *Food*, mollusca and fish. 37. MONODON. 38. BALÆNA. 39. PHYSETER. 40. DELPHINUS.

The System of Mammalia of Cuvier, according to the 2nd Edition of the ' Règne Animal.'

A. Unguiculata.

Sect. a. *With three kinds of teeth.*

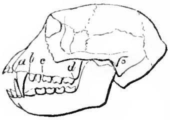
I. BIMANA.

1. HOMO.

II. QUADRUMANA.

1. *Simiæ*, incisors four in each jaw, erect; nails flattened.

Fig. 68.



a, Incisors; *b*, canine or laniary; *c*, false molars, premolars, or bicuspids; *d*, true molars.

α. Inhabiting the Old World; *molars* five on either side of each jaw. PITHECUS, &c.

β. Inhabiting the New World; *molars* six on either side of each jaw. CEBUS, &c.

2. *Lemurini*, incisors more than four either in the upper or lower jaw, procumbent. LEMUR, &c.

III. CARNIVORA.

1. *Cheiroptera*, with membranous expansions between the fingers, and laterally between the extremities.

α. Vespertiliones, with the bones of the anterior extremity disproportionately elongated. PTEROPUS, &c.

β. Galeopitheci, with the fingers and toes of the same length. Galeopithecus.

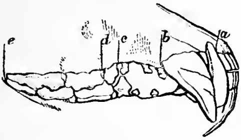
2. *Insectivora,* without lateral membranous expansions; molars cuspidated.

α. With two long anterior incisors, the rest short, the laniaries small. Erinaceus, &c.

β. With the incisors small, the laniaries large. Centetes, &c.

3. *Carnivora,* incisors six in each jaw; molars, some of them sectorial or trenchant.

Fig. 69.



Dentition of Bear.
***a,* Incisors; *b,* laniary; *c,* false molars; *d,* sectorial molar or carnassial; *e,* tuberculate or true molars.**

α. Plantigrada. Ursus, &c.
β. Digitigrada. Canis, Felis, &c.
γ. Pinnigrada. Phoca, &c.

Fig. 70.

Hind extremities, Seal.

IV. Marsupialia.

1. Incisors small; laniaries long; posterior molars cuspidated. Didelphis, &c.

2. Lower incisors two, long; upper ones six. Upper laniaries long and pointed; lower ones small. Phalangista, &c.

3. Lower laniaries wanting; no thumb on the hind feet. Hypsiprymnus.

4. No laniaries. Macropus.

5. Lower incisors two, no laniaries: upper incisors six; two small laniaries. Phascolarctos.

6. Two long incisors in each jaw; no laniaries. Phascolomys.

Sect. b. *Without laniaries; two large incisors distant from the molaries.*

V. Rodentia.

1. With clavicles.

α. Sciuridæ, anterior digits four, posterior five; tail cylindrical and bushy.

β. Muridæ, tail cylindrical, not bushy.

γ. Pedetidæ, anterior digits five, posterior four.

δ. Spalacidæ, anterior digits five, posterior five.

ε. Castoridæ, tail flat and scaly,

2. With imperfect clavicles, or none.

α. Hystricidæ, body covered with spines.

β. Leporidæ, two small incisors behind the two superior large ones.

γ. Caviadæ, no character in common.

Sect. c. *Without incisor teeth.*

VI. Edentata.

1. *Tardigrada;* with a short muzzle. Bradypus, &c.

2. Typical *Edentata;* with an elongated muzzle. Dasypus, &c.

3. *Monotremata;* with marsupial bones and a cloaca. Ornithorhynchus, &c.

B. Ungulata.

a. *Not Ruminants.*

VII. Pachydermata.

1. *Proboscidea;* with a proboscis: *incisors* projecting; *feet* pentadactyle. Elephas, &c.

2. Typical *Pachydermata;* feet tetra-, tri-, or di-dactyle. Hippopotamus, &c.

3. *Solipeda;* feet monodactyle. Equus, &c.

b. *Ruminants.*

VIII. Ruminantia.

1. Without antlers or horns. Camelus, &c.

2. With antlers. Cervus, &c.

3. With horns. Antilope, &c.

C. Mutica.

IX. Cetacea.

1. *Herbivora;* teeth fitted for mastication. Manatus, &c.

2. Typical *Cetacea;* teeth unfitted for mastication, or wanting. Delphinus, &c.

The ideas that have been broached respecting the affinities and classification of the Mammalia after Cuvier, and which are most remarkable for their novelty and boldness, are those which have emanated from the naturalists of the English Quinary school. The founder and the most talented of this sect—Mr. W. S. Macleay—thus enunciates his views of the analogies observable between the principal groups of Mammalia, and those into which the class of birds is resolvable. "Every Mammiferous animal," he says, "may be reduced to these five orders; that is, may be assimilated, in a greater or less degree, to one or other of the following typical forms; viz. Man, the Lion, the Horse, the Whale, and the Mouse. I shall show hereafter how these five orders form a continued series returning into itself, so as to be a natural group. In the mean time, I must recall to the attention of the reader the orders of Birds as defined and arranged by Mr. Vigors; and to which definitions and arrangement I have just applied so severe a test, only to corroborate their accuracy, and to make them display additional harmony.

"When we have heard the Parrot or Mainate speaking; when we have witnessed the former feeding itself as it were with a hand; when, in short, we have reflected on the remarkable intelligence and development of brain throughout the whole order of *Insessores,* to which both birds belong,—there has been no one, perhaps, dull enough not to compare them to *Primates*....I allow, indeed, that it is difficult to follow the opinion of the great naturalist of France, who, ignorant of the true nature of relations of analogy, imagined that the Psittaceous tribe of Birds ought to occupy the first step in the scale of nature below Man; but we cannot help adopting the notion of Linnæus in the '*Systema Naturæ*,' that although not near him in construction, they are yet analogous to him in various important respects. And, adopting this notion, we must place the whole order of *Insessores*, to which *Psittacus* belongs, opposite to the *Primates*, of which Man forms the type.

"The analogies existing between birds of prey and carnivorous quadrupeds having been noticed by Aristotle, who called both groups *Gampsonucha*, were enlarged upon by Plutarch. Among a host of moderns who have been struck with the resemblance, I may particularly mention Linnæus, who in his '*Systema Naturæ*' has expressly called his Accipitres '*Feris analogi*;' and Buffon, who has treated the subject at length and with his usual eloquence. I conceive, therefore, that no one can object to the propriety of my placing the *Feræ* opposite to the *Raptores*.

"The analogy between Aquatic Birds and Aquatic Mammalia scarcely requires the mention of the authority of Linnæus to make it be granted. It is indeed so evident, that Hermann, according to his custom, takes it for a relation of affinity. In both orders the anterior appendages of the vertebral axis dwindling into fins, and the two undivided posterior appendages being placed so far behind on the axis as to show that both were intended for motion in the water rather than on land, are circumstances of themselves sufficient to authorize the placing of the *Cetacea* opposite to the *Natatores*.

"Two orders still remain in each class to be considered: the *Glires* and *Ungulata* among the Mammalia; and among Birds, the *Rasores* and *Grallatores*. The relations of analogy pointed out by Linnæus between Mammalia and Birds are, as Hermann has observed, not always correct; and his errors have arisen from the misfortune of his not detecting the natural group of Aristotle and Ray, which the latter has called *Ungulata*.* Having only been able to seize Aristotle's subdivisions of this group, he lost the parallelism of analogy, and fell, as I shall hereafter show, into very glaring mistakes. In the '*Systema Naturæ*,' however, he has mentioned that very striking analogy which appears between his groups of *Grallæ* and *Bruta*; that is, according to the parallelism of analogy, between the orders of *Grallatores* and *Ungulata*, since the *Bruta*, as we have seen, do not form an order, but only a natural subdivision of the *Ungulata*. That this analogy is demonstrably true, I deduce from the following facts. Of their respective classes, the orders of *Ungulata* and *Grallatores* contain examples of the longest legs in proportion to the body,—witness *Camelopardalis* and *Hæmantopus*. Both orders present us, in groups not exactly aquatic, with instances of the toes soldered together, as in the Horse; or connected together by a web, as in the Flamingo. Both orders present us with the greatest elongation of muzzle or facies,—witness *Myrmecophaga*, or *Antilope* (particularly *A. Bubalus* L.), and *Scolopax*; and also with the most depressed form of muzzle,—witness *Hippopotamus* and *Platalea*, which genera also afford us the truest specimens of Wading *Vertebrata*. In both orders we have the most elongated claws,—witness *Megalonyx* and *Parra*. Both orders afford us the swiftest animals in running,—as the Horse and *Tachydromus*; and the most pugnacious on account of love,—as the Bull and *Machetes*. The Bull moreover and the *Butor* (or *Bostaurus*, for hence comes the bird's name,) afford us the loudest and hoarsest voice of their respective orders: where we have also the most remarkable instances of the upper and under mandibles touching each other merely at their base and point; as *Myrmecophaga*, or the whole of the τα μεν ουκ αμφοδοντα of Aristotle, and *Anastomus* Illig. Both orders exhibit ornamental appendages to the head,—as the antlers of the Stag and the crown of the Crane; and both orders afford us the only instances of true horns,—as *Bos* or *Rhinoceros*, and *Palamedea* L. To see a hundred instances of resemblance, it is only necessary to walk into a museum. I shall therefore only further say, that both orders contain polygamous animals, are generally gregarious, and more graminivorous than granivorous, being essentially inhabitants of marshes and savannahs. Thus then, with Linnæus, I place the *Bruta*, or rather the whole order of *Ungulata* to which they belong, opposite to the *Grallatores*.

"Four orders in each class being now disposed of, it follows by parallelism of analogy, that the *Glires* ought to be placed opposite to the *Rasores*. But setting theory aside,—is this position true in fact?*

"Linnæus, from the above-mentioned error in his series of affinity, considered the *Rasores* to be analogous to his group of *Pecora*. But this group, according to Aristotle and Ray, is only a subdivision of *Ungulata*, which have, I consider, been now proved to be analogous to the *Grallatores*. If, therefore, Linnæus be right in making his *Bruta* analogous to the order of Wading Birds, it follows that his *Pecora* must be so also.

* In making this assertion, Mr. Macleay appears to have overlooked the tabular arrangement prefixed by Linnæus to the more extended characters of his orders of Mammalia. The only fault in the construction of his *Ungulata* is the exclusion of the elephant from that division; for with respect to the edentate *Bruta*, Linnæus and Cuvier correctly interpreted nature in placing them among the Unguiculate Mammalia.

* "The ancient name of *Struthio Camelus*, as well as the form and habits of the Ostrich, show indeed a relation of analogy to the Camel; but then we are to recollect, in the first place, that the Ostrich is at the osculant point or confines of the orders of *Grallæ* and *Rasores*; and secondly, that such slight variations of the parallelism of analogy often appear, although I think it possible that even these are subject to rule."

"The analogy of the *Rasores* to the Ruminating Animals was first, I believe, mentioned by Linnæus in the '*Systema Naturæ*.' It has since his days been copied and copied, until now it almost becomes a sort of heresy to inquire into its accuracy. I am not, however, aware that any reason for this analogy has ever been assigned, beyond the fact,—that one order affords the principal part of those birds which are domesticated by man for purposes of food; and the other, the principal part of quadrupeds which are destined to the same purpose. Now, granting even this domestication not to be the work of art, but to be an analogy really existing in nature, I would observe,—setting the whole family of *Anatidæ* aside, — that the *Glires* afford us many eatable or domesticated animals, such as the *Capromys* and Rabbit; and the *Grallatores* afford us similar instances in the Snipe and *Psophia*. If some *Rasores* be said, like the *Pecora*, to have ornamental appendages to the head, so it must be remembered has the Crowned Crane; whereas no rasorial bird is truly horned, like the *Palamedea*. But it may be worth while to take into consideration successively the grand characteristics of the *Rasores*, as given by ornithologists to distinguish them from all other birds.

"The *Rasores* are, properly speaking, frugivorous birds; by which I do not mean eating fruits only, but all manner of seeds or grain. Now this character of being frugivorous applies much more to the *Glires* than the *Ungulata*, which are truly herbivorous, and only feed on grain in an artificial or domesticated state. To begin, then, with the rasorial or scratching powers of gallinaceous fowls; these are certainly the most burrowing of frugivorous birds: now the most burrowing of frugivorous quadrupeds are certainly not the *Ungulata*, but the *Glires*. These birds are characterised by the shortness of their wings and the weakness of their pectoral muscles. Now if we inquire whether it is among the *Glires* or *Ungulata* that we find the corresponding appendages of the vertebral axis,—that is, the fore-feet most shortened,—the answer will be, certainly not among the *Ungulata;* where, on the contrary, the Giraffe has them extraordinarily lengthened: but among the *Glires* we have the Jerboa, in this respect almost a bird. In general, moreover, this latter order is distinguished, like the *Rasores*, by the strength of those muscles of the two posterior appendages of the vertebral axis or hind-feet, that contribute to locomotion. Gregarious habits distinguish the most of the *Rasores;* so they do in a still more extraordinary manner the *Glires*. Many are insectivorous in both orders, and some are omnivorous. The muzzle or facies of *Glires* is short and round, very like that of *Feræ*, there being a direct relation between the two orders. The facies of *Rasores* is also short and round, very like that of *Raptores* (the order analogous to that of *Feræ*); and there is also a direct relation between these two orders. Many *Rasores* perch and nestle on trees; so do many of the *Glires*. The *Rasores* generally feed on hard grain, which they pick up with their hooked beak, and masticate in a triturating gizzard: the *Glires* feed also on hard substances, which they gnaw with their strong hooked incisors, and masticate with their grinders. In both orders the thumb is very often rudimentary. In both orders the tail varies from an extraordinary length, as in the Squirrel and Pheasant, to being very short, as in the Hare and Partridge.......No orders in their respective classes present the tail so spread out and flattened as the *Glires* and *Rasores*,—witness the Beaver and Peacock. In both orders the sense of hearing is much developed. In both orders we find animals, such as Squirrels and Pigeons, with their toes perfectly free; and others, as *Hydromys* and *Phasianus*, which have them united at the base by a membrane. *Castor* is an aquatic animal, having some relation to *Cetacea; Struthio* is a terrestrial animal, approaching to the *Natatores*. And so on relation comes so fast upon relation, that I know not how we can for a moment hesitate to place the *Glires* opposite to the *Rasores*.

"I conceive it now to be demonstrated, that so far as relates to the analogies existing in nature between the orders of *Mammalia* and *Aves*, we ought to place them thus:—

	Animals typically.	
1. Feræ	Carnivorous	1. Raptores.
2. Primates	Omnivorous	2. Insessores.
3. Glires	Frugivorous	3. Rasores.
4. Ungulata	Frequenting the vicinity of water	4. Grallatores.
5. Cetacea	Aquatic	5. Natatores."

The additional knowledge of the organization of the Mammalia, and especially of the Marsupialia, which has been acquired since the time of Cuvier, has led to corresponding improvements in their classification. A primary binary division of the class based on modifications of the generative function has been established chiefly by the proofs that have been adduced of their co-existence with characteristic conditions of the nervous and vascular systems, as well as of the generative organs themselves. These primary groups or sub-classes I have named Placentalia and Implacentalia, indicative of the adherence of the ovum to the uterus in the one, and its non-adherence, as in the ovo-viviparous reptiles, in the other group.

Taking the orders as they are defined and characterised by Cuvier, the progression of their affinities, so far as they can be given in a linear series, seems to be as follows:*

Class.—MAMMALIA.

Sub-Class.—PLACENTALIA.

Orders. — I. *Bimana*. II. *Quadrumana*.

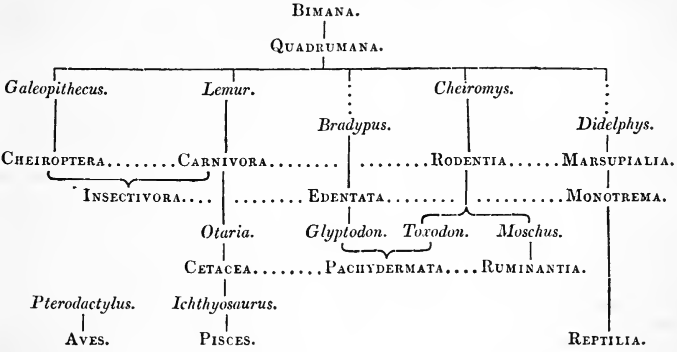
* See the excellent Catalogue of the Mammalia in the Museum of the Zoological Society, by George Waterhouse, Esq. Curator.

III. *Cheiroptera.* IV. *Insectivora.* V. *Carnivora.* VI. *Cetacea.* VII. *Pachyderma.* VIII. *Ruminantia.* IX. *Edentata.* X. *Rodentia.*

Sub-Class.—IMPLACENTALIA.

XI. *Marsupialia.* XII. *Monotremata.*

The aim of the subjoined table is to express the mutual affinities and inter-dependencies of the several orders of Mammalia, and the points at which they are most nearly related to the inferior classes of the vertebrate animals. The annectant genera, some of which are extinct, are printed in italics, the orders and classes in Roman capitals.



(R. Owen.)

MAMMARY GLANDS.—Syn. *Les glandes mammaires*, Fr., *Die Milch, die Brust-drüsen*, Germ. These important organs of secretion are the peculiar characteristic of the highest division of the animal kingdom, *Mammalia*. In a physiological point of view they should be regarded as uterine appendages, as a portion of that series of instruments which Nature has provided in greater or less number, according to the ultimate perfection of the animal, for its gradual development. Their close proximity to the ovarian apparatus in some Mammalia, the cetacea for instance, and their peculiar structure and function in the Marsupiata, confirm this view of their physiological character. It is interesting to trace how gradually they have been removed from their caudal position to the atlantal portion of the body, so that in the human species, where the instincts are subjugated to the control of reason, and the helplessness of the infant has been made the means of moral training to the mother, these organs are brought towards the anterior, the nobler portion of the body.

It must not, however, be supposed that this change of position is sudden, any more than any other step in the scale of progressive development of organized beings. Formerly it was supposed that the re-connection of the ovum to the mother through the medium of bloodvessels collected into a placenta was as universal throughout the class Mammalia as the presence of these glands; but the careful researches of Professor Owen have proved that the Marsupiata and most probably some of the Monotremata form an exception to this rule. The fact is interesting in reference to the present subject from the greater importance which is given to the mamma in consequence of the absence of this vascular connection, and the addition of accessory structures which are absent in the more perfect mammalia.

The arrangement of the secreting membrane of mammary glands has been universally found to be vesiculated, the only difference in different classes of animals consisting in the extent of secreting surface, owing to differences in the size of the cells, and their greater or less concentration within a circumscribed space. This vesiculated structure was described in 1751 by Duvernoi* in the hedgehog (Trans. of the Petersburg Academy), and in the human species it was discovered by Cruikshank, and described in his work on the absorbent glands, the second edition of which was published in 1790. At page 209 his words are, "The acini are small vesicles like Florence flasks in miniature; in these, the arteries secreting the milk terminate; and from these the excretory ducts, or the tubes carrying off the milk take their origin. The existence of such vesicles has been doubted; Dr. Hunter doubted till my injections convinced him of the fact." He then goes on to explain his method of injecting, and concludes by saying that preparations exhibiting this fact may be seen in the anatomical collection in Great Windmill-street, which he had made fifteen years previously.

Müller, to whom the above fact was known, states that Mascagni recognised and demonstrated the vesicular ends of the lactiferous tubes and the absence of all direct communication with the bloodvessels, in his Prodromo della Grande Anatomia, Firenze, 1819.

* Müller de gland. &c.

He refers also to the observations of Buffon on the vesicles of the mamma of the horse, ox, and goat; to those of Von Baer on the vesicles in the mamma of the Delphinus Phocœna, to those of Van Hoeven and Vrolik in the same, and in the Balæna rostrata, and of Meckel in the Ornithorhynchus, adding original observations and illustrations of his own, which demonstrate the same vesiculated structure in the hedgehog and rabbit.

During the course of the present year, 1840, the anatomy of the human breast has been described in a manner by Sir A. Cooper that leaves us nothing to desire, and the minuteness and accuracy of his descriptions are only equalled by the beauty and fidelity of the plates which represent the interesting results of his labours. In our description, therefore, of the human breast we shall do little more than draw from this deep well of instruction.

Human mamma.—*The position* of the human mammæ upon the pectoral muscles is too well known to require any detailed account.

The nipples project forwards and outwards with a slight turn upwards, a direction which is beautifully adapted to the position of the infant when lying in its mother's arms; and the abundance of the lactiferous tubes at the lower portion of the breast, as will be more particularly described hereafter, forms a soft cushion for the head of the child to rest upon.

" The margins of the breast," says Sir Astley Cooper,* " do not form a regular disc, but the secreting structure often projects into the surrounding fibrous and adipose tissue so as to produce radii from the nipple of very unequal lengths, and a circular sweep of the knife cuts off many of its projections, spoils the breast for dissection, and in surgical operations leaves much of the disease unremoved."

At the age of puberty and for some time after, if the breasts are not called upon to perform their office, they present to the touch a dense, compact, smooth, and equal surface; but the distension of the cells in lactation stretches and relaxes the uniting cellular and fibrous membrane, and separates it into " small bodies with indentations around them." This lobulated character does, however, supervene even in childless women upon the cessation of the sexual secretion.

Following the arrangement of Sir A. Cooper, we shall consider the individual parts of the breast from without inwards.

The *nipple* is not placed in the centre of the breast, but nearer the abdominal margin of the gland. In the virgin it is a rounded cone and nearly smooth until puberty, but in the lactating woman forms a flat surface, cribriform with the lactiferous tubes in the centre. " At 16 years it is slightly wrinkled; at 17 it has small papillæ upon its surface; from 20 to 40 years the papillæ are large; from 40 to 50 the nipple becomes wrinkled; from 50 to 60 the nipple is elongated; and in old age it usually has a warty appearance."

This alteration in form during lactation, the extremity becoming the broadest part, renders the adhesion of the child's mouth firmer and more complete.

The nipple or mammilla consists of the common integuments, fascia, milk-tubes, blood-vessels, nerves, and connecting cellular membrane.

The *cuticle* offers no peculiarities except the processes which it sends into the lactiferous tubes, which may be drawn out after continued maceration. Its extreme delicacy is well known to the medical practitioner.

Sir A. Cooper states that the *rete mucosum* " enters with the cuticle into the lactiferous tubes." This may be better seen in the larger quadrupeds, where they terminate a few lines from the extremities of the tubes, forming a fringed edge.

" *Cutis of the nipple*—This forms a considerable portion of the mammilla, and it is divided into two surfaces when the breast is in a state of lactation.

" The first forms the disc or circumference of the nipple, and the second its broad, flat, truncated apex, in which the terminations of the milk-tubes may be seen in numerous orifices.

" The disc is composed of a great number of papillæ, which produce a vascular and sentient surface, and which form its erectile and highly sensitive tissue.

" The direction of these papillæ is from the base towards the apex of the nipple, so that they are pushed back as the mammilla enters the mouth of the child, and thus greater excitement is produced.

" They lap over the truncated extremity of the nipple, forming a foliage upon its apex. This foliated character is one of the consequences of gestation.

" They form in their arrangement upon the nipple broken portions of circles, but when the nipple is elongated and dried they appear to be spiral.

" They form flaps, which are at their edges divided into numerous projections, with serrated depressions between them.

" They are directed forwards towards the apex of the nipple, and the papillæ of the child's lips passing from within outwards, meet them in sucking, are received between them, intermix with them, and produce considerable adhesion and sensation.

" They are very numerous and large for the size of the part, and rather spongy at their extremities.

" They are very vascular bodies, and I have given a figure of them injected. The minute arteries which pass from the base towards the apex of the nipple send numerous branches to the papillæ cutis, which divide into little bushes of vessels in each papilla and terminate in veins.

" The veins also are very numerous, and they will be seen injected, forming bushes similar to the extremities of the arteries.

" The application of the child's lips, the drawing of the nipple in the motions of the child's head, and the suction produced by its mouth,

* Page 13.

produce so much excitement as to occasion erection of the nipple."

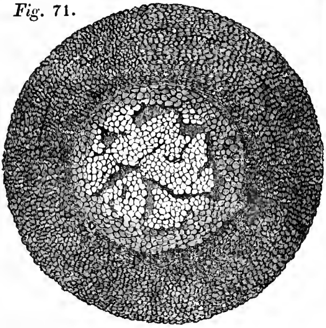
The nipple is carefully connected with the gland by means of a firm fascia encircling the lactiferous tubes derived from the general fibrous tissue of the breast and thorax.

The areola.—This term has been applied to the coloured circle which surrounds the nipple. It is smooth until the period of puberty, when it becomes slightly tuberculated. Its diameter in a child is about half an inch; at puberty and in young women double that size, and during lactation is as much as two inches or more, not again changing except in very old age, when it almost disappears.

The change of the colour of the areola from a reddish tint to a dark brown as the result of impregnation is well known to the practitioner. The cuticle is thin as in the nipple. Speaking of the cutis of the areola Sir A. Cooper observes, that " when the areola is examined with attention after the separation of the cuticle and rete mucosum, its surface is found to be covered with papillæ like those of the nipple, but of smaller size, although stiil extremely distinct. They are smallest at the circumference of the areola, but gradually increase in size as they approach the nipple. They are disposed in circles, their bases fixed in the cutis, and the apex of each is directed towards the nipple, so that they are opposed to the papillæ of the lips of the child. They are very vascular and sensitive bodies". (See *fig.* 71.) The whole structure of the areola points to it as a continuation of the nipple.

The nipple and areola are lubricated by the secretion of especial mucous follicles which surround them, called by Sir A. Cooper *the tubercles of the areola.* " These glands are extremely vascular, lobulated, and cellular. Each orifice opens into an arborescent vessel or vessels." (See *fig.* 72).

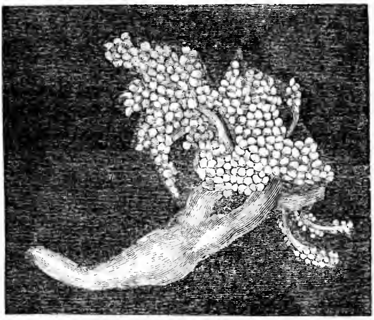
Fig. 71.



A front view of the nipple and areola, shewing the foliated appearance of the papillæ and the numerous but smaller papillæ of the areola.

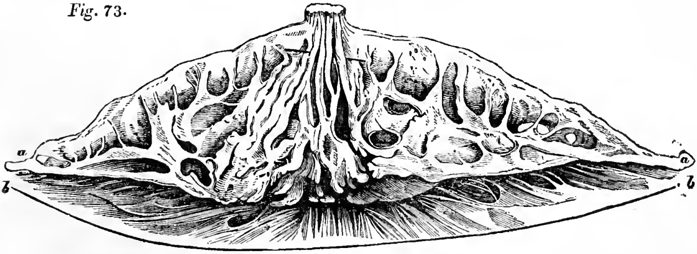
This and the following figures are all taken from Sir A. Cooper's work.

Fig. 72.



A tubercle filled with yellow injection and twenty-three times magnified. These are the tubercles which have been supposed by anatomists to produce milk, and to have communication with the lactiferous tubes, from which, however, they are separate and distinct. They secrete a mucous fluid, which has more the appearance of gruel than milk.

Fig. 73.



A section of the mammary gland through the nipple, shewing the ducts over a bristle unravelled, and proceeding to the posterior part of the gland. The ligamenta suspensoria may be seen passing from the anterior surface of the gland to the skin, supporting the folds or processes of the former, and leaving considerable cavities between them, in which the fat is contained in its proper membrane. The fascia may be observed passing to each extremity of the gland and dividing into two portions; the anterior proceeding upon the surface of the gland to form the ligamenta suspensoria; the posterior behind the gland, sending processes between which a smaller quantity of fat is contained; and both these layers assist in producing the fibrous tissue of the gland. It also sends processes of fascia backwards to join the aponeurosis of the pectoral muscle, b, b, forming the line from one extremity of the gland to the other. The section, therefore, clearly shews the various cords by means of which the breast is slung and sustained. a, a, the fascia.

We must next direct our attention to the internal structure of the breast, first as regards the protective arrangements.

The fascia enveloping the breast, like the tunica albuginea of the testicle, sends in processes to support and protect the secreting membrane of the gland and suspend it in its situation. These processes are all denominated by Sir Astley the *ligamenta suspensoria*, (*fig.* 73). "The ends of these ligaments are spread out and incorporated with the posterior surface of the skin, and give it whiteness and firmness."

The secerning portion of the gland consists of the minute cells which were referred to at the commencement of this article, and we learn from Sir A. Cooper that "their size in full lactation is that of a hole pricked in paper by the point of a very fine pin; so that the cellules, when distended with quicksilver or milk, are just visible to the naked eye. (*Fig.* 74.) They are rather oval than round,

Fig. 74.

Shews the origin of the ducts from the milk cells, (injected with quicksilver and magnified four times.)

being slightly elongated where the bunch of the lactiferous tubes springs from them; but they appear more rounded to quicksilver, and when distended with milk than when filled with wax."

These minute cells or cellules are bound up together so compactly as to form little bodies or "*glandules*," varying in size from a pin's head to that of a small tare. When separated from the rest of the gland but attached to the mammary duct, which originates in separate branches from its cellules, it presents a racemose appearance.

From the *cellules* the milk-tubes originate in a radiate form by small and numerous branches. They increase in size by repeated unions, and terminate by five or six branches in dilatations—the "*reservoirs*" of Sir Astley. "These receptacles are of a conical form (see *fig.* 75) like the mammillary tubes, and they begin from the extremities of the larger branches of the milk-tubes and terminate in the straight ducts of the nipple."

In most other classes of the Mammalia these reservoirs are much larger than in man, where they hardly deserve the title, and in the cow they are so capacious as to be capable of containing at least a quart.

The different ducts of these reservoirs take a straight course, diminishing in size, through the nipple to its extremity, where they terminate in a cribriform manner, with very contracted orifices, varying in size from those of a bristle to a common pin. Their number is about twenty.

Arteries.—The mamma receives its supply of blood from branches of the internal mammary, axillary, and intercostal arteries. Sir Astley divides them into anterior and posterior, the former passing from the axillary artery and the latter from the internal mam-

Fig. 75.

a, a, a, the straight or mammillary tubes, proceeding from the apex of the nipple.
b, b, b, the reservoirs or dilatations of the ducts.
c, c, c, the branches of the mammary ducts.
d, d, d, d, their glandules.

mary, and there is generally a large vessel entering the pectoral or costal surface of the breast and sending its branches through the gland to meet the others upon the surface of the organ. The branches from the axillary are given off by the superior and long thoracic arteries; those from the internal mammary are either derived directly from that vessel or from its intercostal branches. "The arteries upon the cutaneous surface of the breast are lodged in the festoons formed by the ligamenta suspensoria, and proceed to the nipple. There their extreme branches pass each other at the base of the nipple. They send branches forwards from the base to the apex of the nipple, which are parallel to each other and divide into very minute branches which supply the papillæ and the ducts. They also send branches from the base of the nipple backwards into the gland at its centre, and they freely anastomose with those arteries which enter the back of the gland, and they then distribute their ramifications to its substance."

Veins.—"The branches of the veins arising from the nipple pass from its papillæ in parallel branches to its base, and then form radii to an ellipse behind the areola at its margin." Their minute divisions in the papillæ with the corresponding divisions of the artery constitute the erectile tissues. From the ellipsis of veins four principal branches proceed, beside others which are less important: these are distributed on the fore part of the breast, forming a net-work by their free anastomoses.

They terminate, 1st, by two large branches in the axillary vein, and by several branches in the vein accompanying the arteria thoracica longa; 2d, in the cephalic; 3d, in the internal mammary vein by branches which pass between either the first and second or the second and third ribs: 4th, by a deep-seated vein which enters the fourth mammary intercostal vein; 5th, a plexus of veins passes over the clavicle to terminate in the external jugular and subclavian veins.

Nerves.—These are derived from the dorsal division of the spinal cord. The third dorsal nerve descends upon the vessels which are distributed to the nipple and gland, the fourth and fifth are distributed directly to the breast, and the sixth sends some filaments upon the extremities of those arteries which have passed the nipple, but which send branches into the gland. It also receives a supply from the grand sympathetic nerve.

Absorbents.—These vessels are described by Sir Astley Cooper as follows:—

"These vessels always exist in great numbers in the breast, and when the gland is in a state of lactation they are readily injected and demonstrated.

"They are divided into a superficial and deep-seated order. The first are cutaneous and are most connected with the nipple and the mucous glands of the skin, and the second arise from the interior of the glandular and secretory structure of the mamma.

"The superficial arise from the nipple, and they pass principally upon the surface of the gland, behind the skin, on its axillary side.

"In my injections I find them as follows:—

"First, they pass upon and then under the superficial fascia, and between it and the aponeurosis of the pectoral muscle. They are next continued over the intercostal muscles.

"Here they enter the absorbent or cribriform opening, or sometimes there are two openings in the fascia axillæ, as it there passes from the edge of the pectoralis major to that of the teres major and latissimus dorsi muscles, and which fascia shuts up and forms the floor of the axilla.

"Having passed through this fascia into the axilla they enter the first set of axillary absorbent glands, and form a considerable plexus of absorbent vessels between them.

"They then rather descend to the third and fourth ribs to enter another set of absorbent glands, which are placed between the third and fourth ribs and second and third intercostal spaces, and they then ascend to the second rib.

"Here they form a large and elaborate plexus upon the axillary vein, from one to two inches below the clavicle, and reaching the first rib they again enter absorbent glands.

"From these glands, situated upon the first rib, an absorbent trunk is formed, of the size of a large crow-quill, which is placed close to the inner side of the axillary vein and between the first rib and the clavicle, and this absorbent trunk terminates at the angle formed between the right jugular and right subclavian vein, where the absorbents of the right arm and those of the right side of the neck also end in the veins.

"There is an opening formed for this vessel under the costo-clavicular ligament with a distinct margin on each side.

"The place of termination of the absorbents in the vein is a little above and behind a line drawn from the middle of the clavicle above the first rib.

"On the left side the absorbents of the breast form a similar absorbent trunk, which terminates at the angle of the left jugular and subclavian veins, at which angle the thoracic duct also ends.

"Besides this course of the absorbents from the breast and through the axilla there are other absorbent vessels which pass behind the axillary vein, artery, and axillary plexus of nerves to join the absorbents of the arm. They also pass through several absorbent glands, and ascending before the axillary plexus of nerves, they mount behind the clavicle and before the axillary bloodvessels, to terminate on each side at the angle of the jugular and subclavian veins.

"Thus there are two courses of the absorbents from the breast through the axilla; one internal to the bloodvessels and between them and the ribs; the other, which is more external, joins the absorbents of the arm, and passing behind the vessels and nerves of the arm, then crosses the nerves and the axillary artery to enter the angle of the jugular and subclavian veins.

"If, therefore, the absorbent glands in the axilla are obstructed by disease of the breast, other absorbent vessels carry their fluid into the absorbents from the arm, and when their glands are obstructed other absorbent or lymphatic vessels are found to pass behind the scapula from the axilla to enter the cervical glands above and behind the clavicle.

"The absorbents of the sternal side of the nipple principally take two courses.

"The first accompany the vein and the artery to the second intercostal space between the second and third cartilages of the ribs, and penetrating the intercostal muscles, they pass to the anterior mediastinum, where they accompany the internal mammary artery and vein, and enter some absorbent glands.

"A set of absorbent vessels from the sternal side of the breast, placed lower down, enter the intercostal muscles between the fourth and fifth cartilages of the ribs, and join the former in the anterior mediastinum.

"After entering the anterior mediastinum a part of those which pass from the right breast join some vessels from the convex surface of the liver, and are continued into the angle of the right jugular and subclavian veins, whilst those absorbents of the left breast which enter the anterior mediastinum pass to the angle of the left jugular and subclavian veins.

"The deep-seated absorbent vessels which can be best injected from the ducts and milk cellules whilst the breast is in a state of lactation, arise from the mucous membrane of the lactiferous tubes and milk-cells, and form a plexus of great beauty in the interior of the gland.

"These numerous absorbents, as seen in the preparation, unite into two principal vessels, which pass into the axilla, and there enter the same absorbent glands as those which receive the superficial absorbents.

"Those on the sternal side of the nipple pass into the anterior mediastinum, though some of them turn round above the nipple and enter the axillary glands.

"The deep-seated absorbents, many of them, join the superficial upon the convex or cutaneous surface of the breast, and after passing through the glands in the axilla terminate with them at the angle of the jugular and subclavian veins.

"But the absorbents of the concave or costal surface of the breast take a different course. They penetrate the intercostal muscles behind the breast and enter absorbent vessels which accompany the aortic intercostal arteries on the axillary side of the breast, but on the sternal side they join the internal mammary intercostals; the former pass into the thoracic duct in the posterior mediastinum; the latter enter those vessels in the anterior mediastinum which I have already described."

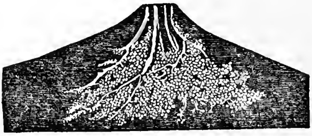
The effect of age upon the mamma is to absorb its glandular structure, to load the ducts with mucus, to obliterate the milk cells, to excessively ossify the arteries, and to thin and wrinkle the nipple, and at length in a great degree to absorb it. But the deposition of fat occupying the place of the glandular structure, the general contour of the breasts in fat persons is maintained.

On the mammary glands in the male.—The credit of discovering the intimate structure of this gland in the male is entirely due to Sir Astley Cooper; nothing, we believe, whatever having been known on the subject previous to his researches. Its size varies in different individuals; it is largest in men of light complexion and effeminate appearance. "The largest male glands which I have seen," says this author, "were found in a man whose testes were remarkably small."

In some persons it is no bigger than a large pea, in others an inch and a half or even two inches. There are papillæ on the nipple and in the areola of the male as in the female, only they are more minute and much less vascular. The cutaneous glands and tubercles are very similar in both sexes.

"The gland is constituted of two parts:—first, of very minute cells, and, secondly, of small conical ducts which divide into numerous branches in the glands, and terminate in straight ducts which end in very minute orifices at the nipple. In their form, in their divisions, and in their course through the nipple, they all form a miniature resemblance of the gland and vessels of the mammary gland in the female." (*Fig.* 76.) The whole is supported by a firm fascia, as in the female.

Fig. 76.



Five ducts of the male gland, injected with quicksilver, exhibiting its ramifications and cells. The ducts divide much in the same manner as those of the female.

Murat and Patissier, in the article Mamma,* refer to a case related by Dr. Renault of an individual whose mammæ were equal in size to those of the female and emitted a serous fluid having the appearance of milk. The organs of generation were diminutive, the testicles about the size of a small nut, and his penis like a mere tubercle, and, even in a state of erection, only an inch and a half in length. Nevertheless he was given to venereal intercourse and all the usual habits of men.

This discovery of the glandular structure of the male breast explains, most satisfactorily, the cases which are on record of the sustenance of the infant by the male parent after the death of the female, the most authentic of which is related by Humboldt in his travels.†

* Dict. des Sciences Méd.
† Vol. iii. p. 58.

Although the usual number of mammæ in the human species is only two, still there are exceptions and instances on record of more having been developed. One of the best authenticated and most recent of these cases is related by Dr. Lee, in the Transactions of the Medical and Chirurgical Society for 1837.*

In this instance "the inferior or pectoral mammæ were fully developed and in the natural situation, and their nipples, areolæ, and glands presented nothing unusual in their appearance. Near the anterior margin of the axilla, a little higher up on each side, was situated another mamma, about one-sixth of the size of the others. The nipples of these were small and flat, but when gently pressed, a milky fluid which had all the external characters of the milk secreted by the other breasts, flowed copiously and readily from several ducts which opened on their extremities. When milk was drawn from the lower breasts, a small quantity usually escaped from the nipples of the superior breasts, and when the draught came into the former, the latter invariably became hard and distended." The flatness of the nipples prevented her suckling her children by them. Dr. Lee, in the above paper, quotes five other cases from foreign authors of quadruple mammæ, also stating that "in some women only one breast has been developed; others have had two nipples placed on one mamma; and a few individuals have had three breasts, two in the natural situation and a third situated in the middle of the two others. Only one case has been recorded of five mammæ in the human subject."†

Comparative anatomy.—In considering this division of our subject we shall especially direct our attention to those points in the anatomy of the mammæ of animals which possess a physiological interest, omitting minute anatomical details unless they bear upon general principles. These organs in the Kangaroo, one of the Marsupiata, as we have already hinted at, are peculiarly formed, for the young of these animals, when first removed from the uterine cavity of its parent, is more like an earth-worm in its appearance than the active animal by which it is produced. So helpless is the condition of this young animal that it has not been inappropriately called a *mammary fœtus*, for the mammæ, in this instance, act at first like a true placenta as a permanent conductor of nutriment, and not, as in the higher Mammalia, a mere storehouse to be resorted to occasionally. Indeed, so close is the union between the parent and its offspring, and so imperfect the power of the fœtus to abstract nourishment by suction, that Geoffroy St. Hilaire had recourse to the hypothesis that there was some vascular connexion. But the imperfect power of the fœtus is compensated by the addition to the breast of a muscular apparatus, which propels forwards the nutritious juices of the mother into the alimentary cavity of the helpless young one. From the interesting account which Mr. Morgan has given of these glands* in the Kangaroo, we shall extract the following particulars.

In this animal there are four teats, two of which, in the virgin state, are at the bottom of a narrow pouch in which they lie hid. It is to one of these teats that the marsupial fœtus is attached immediately after its removal from the uterus, and their size, at first small in accordance with the minute mouth of the animal, increases with its growth. The muscular apparatus above alluded to embraces both the teat and the gland, and acts from the marsupial as its fixed point. The teat is further provided with a true vascular erectile tissue.

The upper or smaller gland is perfectly similar in its organization to the larger, and, notwithstanding the doubts which Mr. Morgan expresses regarding its use, Mr. Owen observed in the instance which he has so carefully recorded in the Philosophical Transactions for 1834, that the fœtus was attached to the upper and not the lower nipples, and "that the nipple in use by the young one of the previous year was the right superior or anterior one." With regard to their minute structure it would appear from the figures of Mr. Morgan that the lacteal tubes originate in plexuses and not in cells, but the text is not very precise on this point.

The consideration of the existence of these organs in those bird-like Mammalia, the Ornithorhynchi, or duck-billed moles of Australia, is interesting. For the beak-bearing mouth of the adult would not lead us to expect the existence of a gland, the secretion of which is usually obtained by the action of a soft mouth convertible into a sucking apparatus.

Nevertheless a distinct mammary gland was described and figured by Meckel in 1826; and an organization of the lips and tongue of the young animal to correspond with it was subsequently described by Professor Owen in the Trans. Zool. Society, vol. i. p. 228, 1834.

According to Meckel this gland is placed on the side of the abdomen between the panniculus carnosus, to which it adheres loosely, and the obliquus descendens abdominis, stretching from the anterior and external margin of the pectoral muscle and inferior extremity of the sternum to the thigh. Its great size is merely one among the many instances which we meet of the comparative want of concentration of individual organs in the lower as contrasted with the higher animals, for the secreting surface itself is much less extensive than in those animals in whom the whole organ is much less.

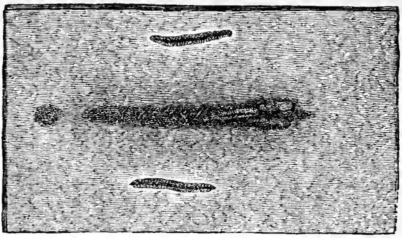
The mammary glands of the Ornithorhynchus are peculiar for the absence of the nipple, a deficiency which is not met in any other class. In the Cetacea it is so completely buried and concealed that it has been described as absent, but it exists perfectly formed, buried in its protecting fissure. The deficiency in the first and concealment in the last

* Page 266.
† Dict. des Sciences Méd. tom. xxxiv. p. 529.

* Linn. Trans. vol. xvii. 1828.

has a relation to the aquatic mode of life, the whole surface of the body being constructed with the view of avoiding friction. The mammary gland in the Ornythorhynchus consists internally of pyriform cœcal pouches, with their bases turned towards the skin, their apices communicating with short excretory ducts; the walls of these pouches are thick and the cavities narrow. As regards simplicity of the internal arrangement of the gland, that in the common porpoise, where the cells and milk tubes are large and diffused, may be placed next in order to the Ornithorhynchus.

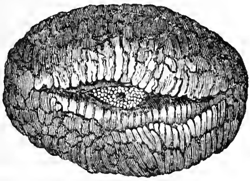
Fig. 77.



Shews the situation of the clefts in the skin of the Porpoise which contain the mamillæ, and which are placed on each side of the anus and os externum vaginæ. They are considerably smaller than nature in this drawing, but figs. 78 *and* 79 *are of the natural size.*

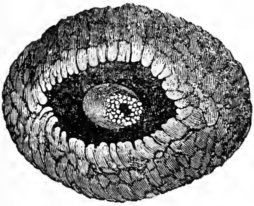
There is no reason for supposing that there is any essential departure from this kind of arrangement of the secreting portion of the gland in different animals, the cellular or vesicular having been met with in all instances where this gland has been carefully injected and unravelled. But the efferent ducts vary considerably. We learn from Sir A. Cooper that the cow, the ewe, the goat, the guinea-pig, and the porpoise, have only one tube in each teat. The pig has two, the rhinoceros has twelve, and the hare and rabbit and the cat and bitch several. " In the Graminivora the reservoirs are enormously large, in the Carnivora comparatively small. In the pig there is scarcely any reservoir; in the porpoise the great enlargement of the milk-tube is a substitute for the reservoir."

Fig. 78.



One of the clefts a little open, to shew the end of the mamillæ buried in it.

Fig. 79.



Shews the cleft more open, exhibiting the nipple and its orifice projecting into it. These clefts are placed in their natural direction in the long axis of the animal, but fig. 77 *is not.*

Morbid anatomy.—It must be clearly understood by our readers that we do not intend to give more than a mere outline of its diseases, and must refer them for more ample information to the admirable works of Sir A. Cooper and others. The diseases of the breast have been divided by Sir A. Cooper into three classes; " first, those which are the result of common inflammation, whether it be acute or chronic. Secondly, into complaints which arise from peculiar or specific action, but which are not malignant, and do not contaminate other structures. Thirdly, into those which are not only founded on local, malignant, and spectfic actions, but which are connected with a peculiar and unhealthy state of the constitution."

Simple inflammation of the breast, like inflammation in every organ where its progress would rapidly prove destructive to its essential structure, is attended with excessive and inordinate pain, and thus gives such warning of the danger that it cannot be disregarded by the sufferer. The fibrous protective covering of the gland, like that of the testicle, prevents inordinate swelling, but occasions greater hardness to the touch. This inflammatory action, usually very unequivocal in its appearance, very rapidly developes pus; the abscess following is troublesome and extremely obstinate in cure; chronic abscess does, however, occasionally occur, and absence of all the usual symptoms of inflammation masks the character of the disease and gives rise to the suspicion that it is a malignant tumour requiring extirpation. Sir Astley relates some cases which came under his notice in which the sense of fluctuation indicated to him the true character of the disease, and others in which the extirpating knife of the surgeon was only arrested by the flow of pus. This same author describes such occasional distension of one of the lactiferous tubes caused by chronic inflammation and obliteration of its aperture as to simulate chronic abscess. The breast is liable to what has been called hydatid disease, of which there are four kinds, one of a malignant nature; the other three are not so. The first has been designated by Sir A. Cooper cellulous hydatids; the second is the sero-cystic tumour of Sir B. Brodie; the third is the animal or globular. Cellulous hydatids are simple bags containing fluid. "The breast gradually swells," says Sir A. Cooper,* "and in the beginning is entirely free from pain or tenderness; it becomes hard, and no fluctuation can then be discovered in it; it continues slowly growing for months and even years, sometimes acquiring very considerable magnitude, the largest I have seen having weighed nine pounds; but in other cases, although the bosom was quite filled with these bags, yet it never exceeded twice the size of the other breast." After a time fluctuation may be felt and the cutaneous veins enlarge, but the breast continues free from pain and the constitution does not suffer. The tumour is moveable and pendulous, in some cases involving the whole gland, in others only a small portion.

"When the swelling,† and the breast in which it is situated, are examined, it is found, upon a careful dissection, that the interstices of the glandular structure itself, and the tendinous and cellular tissue connecting it, are in a great measure filled with fibrous matter, poured out by a peculiar species of chronic inflammation, but in some instances a bag is formed into which a serous, or glairy, or sometimes a mucous fluid is secreted, according to the degree of inflammation attending it, and this fluid, from its viscidity and from the solid effusion which surrounds, as well as from the cyst being a perfect bag, cannot escape into the surrounding tissues; but by its quantity, its pressure, and by the gradual yielding of the bag, it becomes of a very considerable size; and vast numbers of these cysts are found to occupy each part of the breast, producing and supporting a continued but slow irritation, and occasioning an effusion of fibrous matter, by which the breast forms an immense tumour consisting of solid and fluid matter. Within these bags of fluid, hydatids hang by small stalks." "The size of these cells varies from the head of a pin to that of a musket-ball." "When the tumour requires removal for this disease, it is necessary to take away all the hardened and swollen parts of the breast, for they have cysts, or cells, formed in them; and if any cyst be suffered to remain, it will still continue to grow, and the remaining part of the breast to form an hydatid tumour. The great solace to the patient in this disease is, that as it does not contaminate other structures, there is no danger of its extending by absorption, of its producing any complaint beyond the breast, or of its affecting other parts of the body; nor have I seen it seated in both breasts at the same time."

Sir B. Brodie‡ has pointed out an important feature in the development of certain cysts in the breast, which are different from the true hydatid. This consists in the generation of a morbid growth or excrescence from their interior, which becoming organized sometimes entirely fills the cyst so as to convert it into a solid tumour, which ultimately protrudes externally as a fungous growth, and presents a new and formidable appearance. "In this last stage of the disease,* it is evident that spreading ulceration, sloughing and hæmorrhagé, the usual results of an ulcer occurring in a diseased structure, must ensue, and that no remedy is likely to be of any service to the patient, except the removal of the affected parts by surgical operation." The operation is not recommended in the early stages of the disease, as these cysts sometimes become absorbed previously to the development of the fibrous tissue. As the disease is merely local the operation is wholly unattended with danger. The term by which Sir B. Brodie designates these tumours is that of "sero-cystic tumour of the breast." It appears probable that the *bladder scirrhus* of Dr. Benedict is nothing more than this form of hydatid disease.

"The third species of hydatid† which is found in the breast is the animal or globular, and which consists of a bag containing a fluid, which has no vascular connection with the surrounding parts; and it produces within its interior a multitude of bags similar to itself. It is in fact a true entozoon similar in every respect to that found in the brain of sheep and in many other organs of the human frame."

"When one of these hydatids,"‡ says Sir A. Cooper, "is produced in the breast, an inflammation is excited by it, and a wall of fibrine surrounds it, it feels hard, and from the small size of the hydatid a fluctuation cannot be discovered; but as the hydatid grows, although the quantity of solid matter increases, yet as the fluid in the hydatid becomes more abundant, a fluctuation in the centre of the tumour may be ultimately perceived."

The disease is not malignant, and if a simple puncture and evacuation of its contents should not prove effectual in dispersing it, may be removed without danger.

The *chronic mammary* tumour occurs early in life and unconnected with any diseased state of constitution. "It grows," according to Cooper, "from the surface of the breast rather than from its interior, and it therefore generally appears to be very superficial, excepting if it spring from the posterior surface of the breast, when it is deep-seated and its peculiar features are less easily discriminated." These tumours are unconnected with the glandular structure of the breast. Dr. Warren§ relates a case in which he removed one of these tumours from a young woman, who four years after the operation nursed an infant from the same breast. They are extremely moveable, frequently begin without pain, and continue many years without exciting any uneasiness. They vary in size, have a lobulated character, and are invested in a fibrous membrane. "Although these tumours are not in their commencement malignant, and

§ Surgical Observations on Tumours, Boston, 1837, p. 211.

they continue for many years free from the disposition to become so, yet if they remain until the period of the cessation of menstruation they sometimes assume a new and malignant action." The breast is not exempted from the deposit of either cartilaginous or ossific matter, and tumours of this character are occasionally developed in its substance.

The breast is occasionally enlarged by hypertrophy of the adipose tissue. A tumour of this kind, removed by Sir Astley Cooper, is preserved in the Museum of St. Thomas's Hospital, which weighed 14 lbs. 10 oz. The whole structure of the mamma also has been found hypertrophied and the breasts enormously increased in dimensions without being apparently the subject of any disease. That all-pervading poison of some constitutions—the scrofulous tubercular matter—does not leave the mamma exempt from its influence. Sir Astley says that these tumours " can only be distinguished from the simple chronic inflammation of the breast by the absence of tenderness, and by the existence of other diseases of a similar kind in the absorbent glands of other parts of the body." They produce no dangerous effects, and do not degenerate into malignancy.

" The breast is liable to become irritable without any distinct or perceptible swelling, as well as to form an irritable tumour composed of a structure unlike that of the gland itself, and which therefore appears to be of a specific growth." " When the complaint affects the glandular structure of the breast, there is scarcely any perceptible swelling, but one or more of its lobes becomes exquisitely tender to the touch, and if it be handled the pain sometimes continues for several hours." " There is no external mark of inflammation, as the skin remains undiscoloured." " Besides this irritable and painful state of a whole or part of the breast, a tumour sometimes is found distinctly circumscribed, highly sensitive to the touch, acutely painful at intervals, more especially prior to menstruation, very moveable, often not larger than a pea, seldom exceeding the size of a marble; generally one only exists, but in other cases there are several similar swellings."

" Although they continue for years they vary but little in size. I have never seen them suppurate. They sometimes spontaneously cease to be painful, and sometimes disappear without any obvious cause. Upon dissection they are found to be composed of a solid and semi-transparent substance, with fibres interwoven with it, but without any regular distribution, and I have not been able to trace any large filament of a nerve into them." " The pain with which this tumour is accompanied, its tenderness to the slightest touch or to pressure of any kind, the suffering which succeeds examination, distinguish it from the hydatic, the chronic mammary tumour, and the scirrhous and fungous tubercle."

The malignant or incurable diseases of the breast may be classed under two heads, scirrhous carcinoma or cancer, and fungus hæmatodes.

Scirrhus has been again subdivided into genera by different authors, some in relation to their external appearances and situation, others in accordance with their internal structure. Dr. Benedict, Professor in the University of Breslau,* in giving the following arrangement has rather pursued the former plan:—1st. Cutaneous cancer. 2d. True scirrhus; consisting of—1. Nodulated scirrhus; 2. Lard-like scirrhus; 3. Bladder scirrhus.

Müller, in his late work on cancer, which has been translated by Dr. West, describes the different kinds of carcinoma to which the breast, in common with other organs, is liable, not in reference to their seat whether cutaneous or glandular, but in accordance with their intimate structure; and to scirrhus, medullary sarcoma, carcinoma alveolare, and carcinoma melanodes of former authors, has added carcinoma reticulare and fasciculatum. To these we shall return a little further on, dwelling previously on a form of cancer which is not very common but highly important in a practical point of view to the surgeon.

" Cutaneous cancer of the breast," says Dr. Benedict, p. 39, " deserves to be particularly noticed, because most surgeons frequently confound it with the common cancer, from which it, however, materially differs. It never springs in the substance of the organ, but always and solely in the surface of the skin, and most probably from fat and adipose glands of the same. Its form is similar to that of cancer in the face and eyelids, and arises in the same way. At first there is nothing but a little knot, wart, or hard little spot somewhere upon the skin of the breast. This place begins gradually to redden and then passes into a stage of ulceration. The swelling which has hard edges and a hard base spreads out, increasing both in depth and width so as to advance from the skin into the substance of the gland, not passing far, and only very gradually destroying the breast. The glands of the axilla are not attacked so early as in carcinoma of the gland itself, and the hectic fever which ultimately destroys the patient developes itself after a much longer period.

Mr. Travers (Med. Chir. Trans. vol. xvii.) also describes this cutaneous cancer in the following words: " There is a cancerous tubercle of the skin which appears upon the breast as in other parts, connected with a remarkable change in the texture of the skin. The affection of the skin is, I believe, primary. It consists of a brawning induration with extension of the areolæ, a coarseness such as this texture presents when viewed through a magnifier, and which gives it a resemblance to pig's skin. Isolated tubercles of various sizes appear at considerable distances apart: the texture of the subjacent cellular membrane is enormously thickened and has a cartilaginous hardness; and the breast when the skin undergoes this change upon that organ is early and immoveably fixed to the chest." I have drawings of two cases of the kind: one which occurred in the practice of

* Bemerkungen über die Krankheiten der Brust- und Achsel-Drüsen. Breslau, 1825, 4to. p. 59.

Mr. Travers, at St. Thomas's Hospital, the other in the private practice of Mr. South; the former I inspected in company with that gentleman. The post-mortem appearances were interesting from the immense crop of white hard tubercles which were found studding the pleura costalis.

Dr. Benedict considers that "the primary skin disease can be removed almost always with a favourable result if the operation is performed previous to enlargement of the neighbouring glands, disease of the parenchyma of the mamma, or constitutional fever."

The ordinary scirrhus of the mamma in its early stages usually presents itself to the surgeon as a hard tumour, situated *in* not *on* the glandular substance of the breast. At first it is comparatively moveable, but it cannot be moved independent of the structure which surrounds it, and in the progress of development it soon contracts adhesions by means of root-like prolongations with the whole mamma. Its surface varies, not decidedly nodulated nor yet uniformly smooth; not tender to the touch, though it may be the seat of sharp lancinating pains. As the tumour increases, its adhesions extending on all sides, the nipple becomes drawn in, and its most prominent surface assumes a dusky hue. The constitution now begins to suffer, the glands in the axilla enlarge, and at this period there is no difficulty in distinguishing the nature of the disease. In its early stage it might be confounded with a tumour which Mr. Travers in his paper just referred to has thus described: "There is a tumour met with in the breasts of young women, more like a shelled walnut in point of size and nodosity than any thing to which I can compare it. It is of a stony hardness, and it is not reduced by regulated equal compression, mercury, iodine, or blisters. It is an enlargement and partial cohesion of the lactiferous tubes in a cluster, in one or more places, and which disposition in a less degree pervades the ducts throughout the organ." The absence of lancinating pains, constitutional disturbance, and the peculiar countenance attendant on malignant disease, assist the surgeon in his diagnosis. The earlier period of life at which it makes its appearance is also a circumstance worthy of attention.

Müller describes scirrhus, or carcinoma, simplex (syn. carcinoma fibrosum) as "irregular in form,* not lobulated, hard and resisting the knife, and presenting, when divided, a greyish appearance which has but very little similarity to cartilage. Whitish bands are not invariably present. Scirrhus of the mammary gland occasionally shews, here and there, whitish filaments, some of which are hollow, and contain a colourless, whitish or yellowish matter. Probably this appearance of white filaments is the result of thickening of the walls of the lactiferous tubes and lymphatics, and this idea is confirmed by the absence of these filaments from scirrhus of non-glandular parts. The mass of scirrhus is composed of two substances, the one fibrous, and the other grey and granular." The fibrous substratum is composed of a very irregular net-work of firm bundles of fibres. The grey consists of microscopic, formative globules, but slightly adherent to each other; they are transparent hollow cellules, from 0.0048 to 0.00166 or 0.00130 of an English inch in diameter, some of them exhibiting a distinct nucleus. They have no connection with the fibrous structure."

Carcinoma reticulare, Müller says,* "occurs more frequently than carcinoma simplex. On making a section of it, it may be immediately distinguished from the latter by the white reticulated figures intersecting the grey mass, which are perfectly evident to the naked eye. It acquires a large size more readily than carcinoma simplex, and is further distinguished from its tendency to assume a lobulated form. It sometimes approaches the consistence of scirrhus, at other times it is softer and more nearly resembles fungus medullaris." Though its consistence varies, its structure always remains the same, and with the exception of cancer alveolaris, no form of carcinoma can be so readily distinguished.

Carcinoma alveolare, though usually found in the stomach, occasionally attacks the breast, and a very good specimen of it is deposited in the museum of St. Thomas's Hospital. This disease, like the former one, consists of innumerable white fibres and lamina crossing each other in all directions, and having their interspaces occupied by cells which vary in size from that of a grain of sand to that of a large pea. For the history of the development of this and other forms of cancer see PRODUCTS, MORBID.

Soft cancer, fungus hæmatodes, and *medullary carcinoma*, are one and the same disease. It forms a soft elastic swelling, giving something of the sensation to the fingers of deep-seated fluid, increases rapidly, and is seldom confined to any single organ in the body. It occurs earlier in life than scirrhus, and is more decidedly a constitutional disease. "The tumour with which alone this is liable to be confounded," says Mr. Travers, "is the hydatid breast, as it is called, and there is sufficient resemblance in the rounded outline, the elastic resistance, the absence of glandular affection, the distressing inconveniences of size, weight, and distension, the turgid veins and livid discoloration of the surface, to create some hesitation. But in the medullary disease it seldom happens that the health is not affected, whereas in the hydatid breast it is undisturbed; the figure of the medullary tumour is less uniform, being marked by dark tuberous elevations and immovably fixed to the side by the prolongations of the diseased growth in one or more parts of its circumference; whereas the hydatid tumour, notwithstanding its oftentimes enormous bulk, is globular and remains perfectly detached and pendulous. The main distinction is that the mammary gland is not, in my experience at least, the seat of the medullary or fungoid disease as it is of the hydatid.

* West's Translation, 41.

* Page 45, loc. cit.

"In proportion as the malignant fungus is recent and of small dimensions, is the difficulty of diagnosis from the hydatid cyst, for the fungus, as I have before said, ordinarily commences on the interior of a cyst containing a fluid, from the vascular lining of which it hangs like a fringe, and it is common to find more than one, often several contiguous cysts, in the early stage of the disease. As the fungi grow, the cysts burst and are blended in the same mass. From this account it will appear that there is sufficient analogy between the hydatid and fungoid disease in its incipient state to require more aids to diagnosis than those derived from manual examination. We sometimes meet with puzzling analogies in these diseases."

"The relation of medullary sarcoma," says Müller, "to scirrhus or carcinoma simplex is displayed by the fact that after amputation of a scirrhous breast, real fungoid tumours may occur in other parts, as many observations of Zauptaft, Cruveilhier, and others abundantly shew. This affinity is further illustrated by microscopic examination, which shews that many structures comprehended under the generic term of fungus medullaris differ greatly from each other, and have nothing in common but the softness of their texture." Müller therefore employs the term fungus medullaris "as a collective name for different forms or stages of developement of soft cancer, which undergo imperceptible transitions into each other." The following are the varieties for a knowledge of the minutiæ of which we must refer our readers to the original.

"1. Carcinoma medullare, abounding in roundish formative globules which make up the greater part of the medullary mass, though intersected by a delicate fibrous net-work.

"2. Carcinoma medullare, with an exceedingly soft cerebriform base composed of pale elliptical bodies without caudate appendages.

"3. Carcinoma medullare, with caudate or spindle-shaped corpuscules.

"*Carcinoma fasciculatum* (syn. hyacinum.) —Among the structures commonly included under the name fungus medullaris, are some altogether fibrous in their texture, and which correspond with other forms of that disease only in the softness of their tissue. The fibrous structure of these growths is immediately evident on breaking or dividing them; when torn they do not crumble, but are readily rent in the direction of the fibres. If examined under a microscope they display neither the cellular globules of other varieties of carcinoma, nor the caudate corpuscules which give a fibrous appearance to some forms of fungus medullaris."

Mr. Travers, in the paper previously referred to, says that "certain anomalous morbid changes, as large fungous excrescences and deep cavernous fetid ulcers, are now and then the sequelæ of tumours in the female breast which are in a loose and slovenly classification termed cancerous. They are not so; but they are almost as incapable of being conducted to a curative termination as if they were; their progress can scarcely be said to affect the health, being remarkable for its slowness and freedom from pain." He also describes an excoriation of the integument around the nipple gradually extending over the breast, accompanied by an ichorous exudation which remains in the same incurable state many years, and ultimately throws up a broad toad-stool fungus exquisitely irritable and much disposed to bleed. It affects neither the glands nor health."

Melanosis or black cancer has been met with in the breast, but we believe never as a primary disease, the breast having been attacked subsequently to other tissues. Breschet, in his treatise on this disease, gives a representation of it in this organ. There is a preparation of it in the museum of Bartholomew's Hospital. It is considered by Müller as "merely a variety of cancerous degeneration, and terminates in the same way as other forms of carcinoma."

"Microscopic examination," says Müller, "detects two forms of melanotic structure. In both instances the basis of the structure is formed of a fibrous network, the stroma of melanosis, within the meshes of which the melanoid matter is deposited. This matter is generally composed of cells, filled with yellowish or blackish green granules. These cells are and always continue to be free, never becoming coherent. Their forms are very various. Many, indeed most, are round, oval, or irregular; some are elongated; a few actually caudate, terminating at one or both extremities in a point or in a fibril. Still more rarely the cells present several points. They are real pigment cells." This author discovered in one of the larger cells a nucleus with its nucleolus, independently of the pigment granules. We cannot conclude this article more satisfactorily than by quoting from the same accurate observer, Mr. Travers, of whose observations we have already so fully availed ourselves.

"No description can comprehend all the varieties of tumour to which this organ is liable, nor does any share of experience enable the nicest observation to suggest an infallible clue to their nature. We have sometimes only manipulation to depend upon, which is an art imperfectly cultivated by scientific surgeons. Cases now and then arise about which the most accurate observers are liable to error. True it is this does not frequently happen in the distinction between innocent and malignant growths. The several species of innocent tumours already enumerated may all be distinguished from scirrhus with comparatively little difficulty; but if any doubt exists we must consider the age, habits, and circumstances of the patient. For example, we should ascertain if marks of scrofula are present; if the uterine functions are regular and healthy; if the tumour can be referred to violence in the commencement, which from the exposed situation of the organ is far from uncommon; if more than one lump exists in the same breast; if both breasts are infected; if painful, the character of the pain; if any absorbent glands are altered in the neighbourhood and how. How many cases of breast tumour are in the recollection of experienced surgeons which have been dispersed by some one or other of the remedies in ordinary use, local or constitutional; and how many that have resisted all and remained stationary for years, the patient's mind having been tranquillized by the assurance of their innocency. Doubtless on the other hand a fatal result has sometimes administered a silent but painfully intelligible reproof to the over-confidence of the surgeon."

(Samuel Solly.)

MARSUPIALIA, (*Marsupium*, a pouch,) Eng. *Marsupials;* Fr. *Marsupiaux;* Ger. *Beutelthiere.*

Essential external character.— Mammalian quadrupeds, distinguished by a peculiar pouch or duplicature of the abdominal integument, which, in the males, is everted and contains the testes; in the females is inverted, covering the mammæ, and generally sheltering the young for a certain period after their birth.

Essential internal character.—In both sexes two supplementary trochlear bones are articulated to the anterior part of the brim of the pelvis, around which play the muscles embracing and supporting the testes in the male, and the mammary glands in the female; these bones, from their connexion with the pouch, are called "marsupial."

The quadrupeds associated together by the common external and osteological characters above defined, are ovo-viviparous or implacental,* the vascular layer of the allantois not being developed, so as to organize the villi of the chorion, or to form cotyledons or a placenta. The marsupial also differ from the placental Mammalia in other important parts of internal organization, as in the structure of the brain and of the heart, and in the condition of the sanguiferous and absorbent systems; and they present remarkable modifications of the genital apparatus in both sexes.

Classification.—The Marsupial animals are generally of small size; some, as the Pigmy Opossum *(Petaurus pygmæus)*, and Dwarf Phalanger *(Phalangista nana)*, are less than the common mouse: the largest known existing species is the common or Great Kangaroo *(Macropus major)*. With the exception of the Virginian Opossum, all the Marsupialia are confined to the southern hemisphere of the globe, and they are principally natives of Australasia, to which part of the world several remarkable genera are peculiar, and where, with a few exceptions, as certain Cheiroptera and a few Rodent genera, as *Hydromys*, *Hapalotis*, and *Pseudomys*, all the known aboriginal mammals are Marsupial or Monotrematous.†

It is in the Australian continent that we perceive the Marsupial quadrupeds typifying, so to say, or playing corresponding parts with those allotted to the placental Mammalia in a larger theatre of the habitable surface of the earth. The carnivorous Thylacines* and Dasyures,† for example, are the pigmy destructives of the country, committing occasional ravages among the sheep and poultry, but not disdaining dead animal matter or garbage.

The species of *Phascogale*, *Myrmecobius*, and *Perameles* represent the placental Insectivora. Many Marsupials which live in trees have an omnivorous or vegetable diet; these in their prehensile tail and hinder thumb typify the *Quadrumana;* and one species, the tailless Koala, seems to represent the American sloths or the arboreal sun-bears of the Indian Archipelago.

Another species of Marsupial, the Wombat, presents the dentition which characterizes the placental Rodentia; and the Petaurists, like the flying squirrels, have a parachute formed by broad duplications of the skin extending laterally between the fore and hind legs.

The Kangaroos are the true herbivorous *Marsupialia*, and many interesting physiological conditions present themselves to the mind in contemplating the singular construction and proportions of these animals. It would appear that the peculiarities of their gestation rendered indispensably necessary the possession of a certain prehensile faculty of the anterior extremities, with a free movement of the digits and a rotatory power of the fore-arm, in relation to the manipulations of the pouch and of the embryo therein protected and matured. At the same time an herbivorous quadruped must possess great powers of locomotion in order to pass from pasture to pasture, and to avoid its enemies by flight. These powers, as is well known, are secured to the herbivorous species of the placental Mammalia by an ungulate structure of four pretty equally developed members. Such a structure, however, would have been incompatible with the procreative economy of the Kangaroo. It is, therefore, organized for a rapid course by an excessive development of the hinder extremities, and these alone serve the animal in flight, which is performed by a succession of extensive bounds. The tail, also, is of great power and length, and, in the stationary position, the body is supported erect on the tripod formed by the tail and hind legs, while in easy progression the tail serves as a crutch, upon which and the fore feet the body is sustained while the hind legs are swung forwards.

As the Australian Continent, the great metropolis of the Marsupial quadrupeds, still remains but very partially explored, and as new species and even genera of Marsupials continue at each expedition to reward the researches of the scientific traveller; and as, moreover, the recovery of two lost but distinct genera from the ruins of a former world makes it reasonable to suppose that other types of Marsupials remain still hidden in the crust of the earth, it can hardly be expected that the zoologist should be able to arrange in a natural series, with easy transitions according to the

* On the Generation of the Marsupialia, Philos. Trans. 1834, p. 333.

† The Dingo or Wild Dog is without doubt a comparatively recent and accidental introduction.

* The Hyæna of the Colonists.

† The Devil, Native Cat, &c. of the Colonists.

order of their affinities, the few and diversified forms of this implacental group which are at present known.

In the subjoined classification the modifications of the digestive system have been taken as the guide to the formation of the primary groups of the Marsupialia.

The Continent, however, in which the Marsupials exist in greatest number and variety, is characterized by the paucity of organized matter upon its surface, and consequently few of the species are nourished by a well-defined diet. No large carnivorous quadruped could without much difficulty have found subsistence in the wilds of Australia, prior to the introduction of civilised man and his attendant herds; and we find, in fact, that the native genera which are the most decidedly carnivorous do not include species larger than the dog. We can only reckon among these strictly carnivorous species the Thylacines and the Dasyures; and, on the other hand, not more than two or three Marsupial genera feed exclusively on vegetable substances. The remainder derive a promiscuous nutriment from dead or decaying animal and vegetable matter, crustacea, and the refuse of the sea-shore, insects in their perfect and larva states, live birds, young and succulent sprouts, leaves, fruits, &c. The terms, therefore, which will be given to the different primary subdivisions in the present classification of the Marsupialia must not be understood to indicate strictly or exclusively the nature of the food of the species severally included in these groups, but rather their general tendency to select for their support the substances implied by those designations.

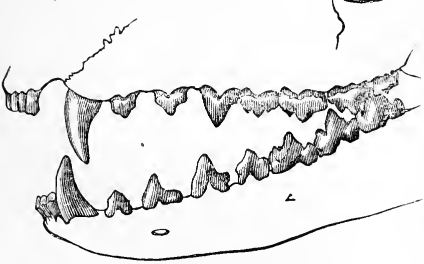
*Classification of the Marsupialia.**

Tribe I. *SARCOPHAGA.*

The genera in this tribe are characterized by an important anatomical condition, viz. the absence of an *intestinum cæcum*.

Genus 1. THYLACINUS. (*Fig.* 80.)

Fig. 80.



Thylacinus Harrisii, one-third natural size.

Incisors $\frac{4-4}{3-3}$; canines $\frac{1-1}{1-1}$; premolars $\frac{3-3}{3-3}$; molars $\frac{4-4}{4-4}$: $= 46$.

The incisors are of equal length and regularly arranged in the segment of a circle with an interspace in the middle of the series of both jaws. The external incisor on each side is the strongest. The laniary or canine teeth are long, strong, curved, and pointed, like those of the dog tribe. The spurious molars in this as in all other Marsupials have two roots; their crown presents a simple compressed conical form, with a posterior tubercle which is most developed on the hindmost. The true molars in the upper jaw are unequally triangular, the last being much smaller than the rest; the exterior part of the crown is raised into one large pointed middle cusp and two lateral smaller cusps obscurely developed; a small strong obtuse cusp projects from the inner side of the crown. The molars of the lower jaw are compressed, tricuspidate, the middle cusp being the longest, especially in the two last molars, which resemble closely the sectorial teeth (*dents carnassiers*) of the dog and cat.

The fore feet are 5-digitate, the hind feet 4-digitate. On the fore foot the middle digit is the longest, the internal one or pollex the shortest; but the difference is slight. On the hind foot the two middle toes are of nearly equal length and longer than the two lateral toes, which are equal. All the toes are armed with strong, blunt, and almost straight claws.

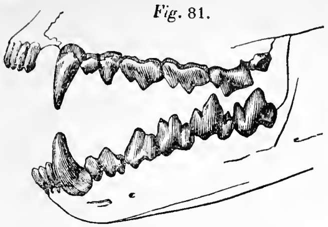
The only known species of this genus,—the Thylacine (*Thylacinus Harrisii*, Temm., *Didelphys Cynocephalus*, Harris,) is a native of Van Dieman's Land, and is called by the Colonists the "Hyæna." It is the largest of the carnivorous Marsupials, equalling in size the shepherd's dog, but is of a broader build, and stands lower on its legs. Its head is of disproportionate magnitude. The principal characteristic of its colour is the transverse black bands which traverse the back. It dwells in caverns and holes in the rocks, and seeks its prey by night, devouring the smaller native quadrupeds, and at the present day committing destructive ravages on the numerous flocks of sheep which have been introduced by the European settlers into the island. Even the spines of the Echidna seem to be no defence against the destructive and voracious propensities of the powerful Thylacine, for the partly digested remains of one of these monotremes have been found in its stomach.

In confinement the Thylacine utters from time to time a short guttural cry, and appears in the daytime exceedingly inactive and stupid, presenting an almost continual movement of the nictitating membrane of the eye.

* Proceedings of the Zoological Society, Jan. 8, 1839. The series of skulls carefully prepared by Mr. Waterhouse at the Zoological Society have afforded me the chief materials for the illustrations of the dental formulæ of the different Marsupial genera.

Genus DASYURUS. (*Fig.* 81.)

Fig. 81.



Dasyurus Ursinus, one-third natural size.

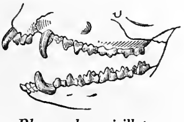
Incisors $\frac{4-4}{3-3}$; canines $\frac{1-1}{1-1}$; præmolars $\frac{2-2}{2-2}$; molars $\frac{4-4}{4-4}$: = 42.

The eight incisors of the upper jaw are of the same length and simple structure, and are arranged in a regular semicircle without any median interval. The six incisors of the lower jaw are similarly arranged, but have thicker crowns than the upper ones. The canines present the same or even a greater relative development than in the Thylacine: in an extinct species of *Dasyurus** they had the same form and relative proportions as in the Leopard. The spurious molars have a pointed compressed triangular crown with a rudimental tubercle at the anterior and posterior part of its base. The grinding surface of the true molars in the upper jaw is triangular; the first presents four sharp cusps, the second and third each five, the fourth, which is the smallest, only three. In the lower jaw the last molar is nearly of equal size with the penultimate one, and is bristled with four cusps, the external one being the longest: the second and third molars have five cusps, three on the inner and two on the outer side; the first molar has four cusps: these are all sharply pointed in the young animal, in which the posterior tubercle of the posterior molar in the lower jaw is divided into two small cusps.

The carnivorous character of the above dentition is most strongly marked in the Ursine Dasyure or *Devil* of the Tasmanian Colonists, the largest existing species of the genus, and a most pestilent animal in the poultry-yard or larder.

Genus PHASCOGALE. (*Fig.* 82.)

Fig. 82.



Phascogale penicillata.

* *Dasyurus laniarius,* Owen: the fossil remains of this species were discovered with those of two gigantic species of Kangaroo in the bone-caves of Wellington Valley, Australia, by Major, now Sir Thomas, Mitchell.

Incisors $\frac{4-4}{3-3}$; canines $\frac{1-1}{1-1}$; præmolars $\frac{3-3}{3-3}$; molars $\frac{4-4}{4-4}$: = 46.

In the present dental formula may be discerned a step in the transition from the Dasyures to the Opossums, not only in the increased number of spurious molars, but also in the shape and proportions of the incisors. In the upper jaw the two middle incisors are longer than the rest, and separated from them by a brief interval; they are more curved and project more forward. The three lateral incisors diminish in size to the outermost. The middle incisors of the lower jaw also exceed the lateral ones in size, and project beyond them but not in the same degree, nor are they separated from them by an interval, as in the upper jaw. The canines are relatively smaller than in the Dasyures. The spurious molars present a similar form, but the third in the lower jaw is smaller and simpler than the two preceding ones. The true molars resemble those of the Dasyures.

The general character of the dentition of these small predatory Marsupials approximates to the insectivorous type, as exemplified in the Shrew, Hedgehog, &c. among the placental Mammalia, and corresponds with the food and habits of the species which thus lead from the Sarcophagous to the Entomophagous tribes.

The interval is further diminished by a lost marsupial genus which forms one of the ancient Mammalia that have rendered the oolitic formations at Stonesfield so celebrated. This genus, which I have called *Phascolotherium*, presents the same numerical dental formula as in *Phascogale*, viz.

Incisors $\frac{?-?}{3-3}$ or 4—4; canines $\frac{?-?}{1-1}$; præmolars $\frac{?-?}{3-3}$; molars $\frac{?-?}{4-4}$.

But the incisors and canines are separated by vacant interspaces, and occupy a large proportional space in the dental series: the true molars resemble those of *Thylacine*.

Tribe II. *ENTOMOPHAGA.*

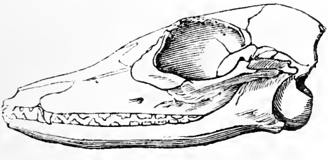
This is the most extensive and varied of the primary groups of the Marsupial order. In the system of Cuvier, the species of this tribe are united with those of the preceding to form a single group characterized by the presence of long canines and small incisors in both jaws: but in most of the Entomophagous genera of the present classification, the canines present a marked inferiority of development, and the species are consequently unable to cope with animals of their own size and grade of organization, but prey, for the most part, upon the smaller and weaker classes of invertebrate animals. Their intestinal canal is complicated by a moderately long and large cœcum; and while, in the *Sarcophaga*, the feet are constructed upon the plan of those of the ordinary placental Digitigrades, they offer in the present tribe a variety of well-marked modifications, according to which the species may be arranged into gressorial, saltatory, and scansorial groups.

α. Gressoria.

Genus MYRMECOBIUS.

The only known existing representative of this family is the animal described by Mr. Waterhouse, which constitutes the type of his genus *Myrmecobius*, and of which the following is the remarkable dental formula. (*Fig.* 83.)

Fig. 83.



Myrmecobius fasciatus.

Incisors $\frac{4-4}{3-3}$; canines $\frac{1-1}{1-1}$; præmolars $\frac{3-3}{3-3}$; molars $\frac{6-6}{6-6}$: = 54.

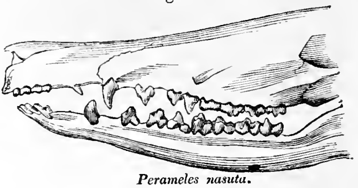
From this formula it will be seen that the number of molars, eighteen in both jaws, exceeds that of any other known existing marsupial, and nearly approaches the peculiar dental formula of the extinct *Thylacotherium*,* and that which characterizes some of the existing Armadillos. The resemblance to the genus *Dasypus* is further carried out in the small size of the molar teeth, their separation from each other by slight interspaces, and their implantation in sockets, which are not formed upon a well-developed alveolar ridge or process. The molars, however, present a distinct multicuspidate structure, and both the true and false ones possess two separate fangs, as in other Marsupials. The inferior molars are directed obliquely inwards, and the whole dental series describes a slight sigmoid curve, (*fig.* 97.) The false molars present the usual compressed triangular form with the apex slightly recurved; and the base more or less obscurely notched before and behind. The canines are very little longer than the false molars; the incisors are minute, slightly compressed and pointed; they are separated from each other and the canines by wide intervals.

The Myrmecobians are insectivorous,† and shelter themselves in the hollows of trees, frequenting most, it is said, those situations where the Port-Jackson willow abounds. In the structure and proportions of its hinder feet, *Myrmecobius* resembles the Dasyurine family; and in the slightly developed canines, the smooth external surface of the skull, the breadth between the zygomata, and the absence of the interparietal ridges, as well as in its general external form and bushy tail, it offers an especial approximation to the genus *Phascogale*.

β. Saltatoria.

Genus PERAMELES. (Bandicoots, *fig.* 84.)

Fig. 84.



Perameles nasuta.

Incisors $\frac{5-5}{3-3}$; canines $\frac{1-1}{1-1}$; præmolars $\frac{3-3}{3-3}$; molars $\frac{4-4}{4-4}$: = 48.

This dental formula characterizes a number of Marsupials commonly known in Australia by the name of *Bandicoots*; the hind legs are longer and stronger than the fore, and exhibit in a well-marked manner the feeble and slender conditions of the second and third digits counting from the inside, and the sudden increase in length and strength of the fourth and fifth, or two outer toes, which are chiefly subservient to locomotion. In consequence of the inequality of length in their extremities the mode of progression in the Bandicoots is by bounds, the hind feet being moved together, and alternately with the fore feet, as in the hare and rabbit, and the crupper is raised higher than the fore-quarter. The teeth which offer the greatest range of variation in the present genus are the external or posterior incisors and the canines: the molars, also, which originally are quinque-cuspidate, have their points worn away, and present a smooth and oblique grinding surface in some species sooner than in others.

The Bandicoots which approach nearest to the *Myrmecobius* in the condition of the incisive and canine teeth, are the *Perameles obesula and P. Gunnii.* There is a slight interval between the first and second incisor, and the outer or fifth incisor of the upper jaw is separated from the rest by an interspace equal to twice its own breadth, and moreover presents the triangular pointed canine-like crown which characterizes all the incisors of *Myrmecobius*; but the four anterior incisors are placed close together and have compressed, quadrate, true incisive crowns. From these incisors the canine is very remote, the interspace being equally divided by the fifth pointed incisor, which the canine very slightly exceeds in size. In *Peram. nasuta* the incisor presents the same general condition, but the canines are relatively larger, In *Per. Gunnii*, the outer incisor is closer to the others, which it also more nearly resembles in form than in the preceding species; but in *Per. Lagotis*, it is not separated from the rest by a wider interval than that which intervenes between the first and second incisor. In both

* This small Insectivore, of which the marsupial character is doubtful, had twenty-four molars in each jaw.—See *Geol. Trans.* New Series, vol. vi. part 1.

† Mr. Gould informs me that they feed exclusively on ants.

the preceding Bandicoots the canines are long and well developed, but the true molars have the grinding surface worn down flat in the full-grown specimens which I have had the opportunity of examining.

The marsupial pouch in the Bandicoots, at least in the full-grown females of *Per. nasuta*, *Per. obesula*, and *Per. Lagotis*, has its orifice directed downwards or towards the cloaca, contrariwise to its ordinary disposition in the Marsupials: this direction of the pouch evidently relates to the procumbent position of the trunk when supported on the short fore and long hind legs. In the stomach and intestines of a *Perameles obesula* I found only the remains of insects; and in the examination of the alimentary canal of a *Per. nasuta*, Dr. Grant obtained the same results. Nevertheless the *Perameles Lagotis*, lately living at the Zoological Gardens, refused meat and meal-worms, and subsisted on vegetable food exclusively.

Genus CHŒROPUS.

The singular animal on which Mr. Ogilby has founded this genus, is briefly noticed and figured in Major Mitchell's Australia, (Vol. ii. pl. 38, p. 131,) and the individual described is preserved in the Colonial Museum, at Sydney, N. S. Wales, (No. 35 of Mr. Geo. Bennett's Catalogue.)

It would appear that the two outer toes of the fore foot, which are always very small in the true Bandicoots, are entirely deficient in the *Chæropus*, unless some rudiments should exist beneath the skin; at all events only two toes are apparent externally; but they are so developed and armed as to be serviceable for burrowing or progression. The inner toe is wanting on the hind-foot. Dental formula:

Incisors, $\frac{4-4}{3-3}$; canines, $\frac{1-1}{1-1}$; præmolars, $\frac{3-3}{3-3}$; molars, $\frac{4-4}{4-4}$: $= 46$.

All the teeth are of small size; the canines resemble the spurious molars in size and shape, and these are separated by intervals, as in *Myrmecobius*. The marsupium opens downwards in the *Chæropus*, as in the true Bandicoots. The species described has no tail. The genus would seem by its dentition to rank between *Myrmecobius* and *Perameles*. Its digital characters are anomalous and unique among the Marsupialia, but are evidently a degeneration from the Saltatorial or Bandicoot type.

γ. Scansoria.

Genus DIDELPHYS, (Opossums, *fig.* 85.)

These Marsupials are now exclusively confined to the American Continents, although the fossil remains of a small species attest their former existence in Europe contemporaneously with the *Palæothere*, *Anoplothere*, and other extinct *Pachyderms*, whose fossil remains characterize the Eocene strata of the Paris Basin. The dental formula of the Genus *Didelphys* is,—

Incisors, $\frac{5-5}{4-4}$; canines, $\frac{1-1}{1-1}$; præmolars, $\frac{3-3}{3-3}$; molars, $\frac{4-4}{4-4}$: $= 50$.

The Opossums resemble in their dentition the

Fig. 85.

Didelphys Virginiana.

Bandicoots more than the Dasyures: but they closely resemble the latter in the tuberculous structure of the molars. The two middle incisors of the upper jaw are more produced than the others, from which they are also separated by a short interspace. The canines are well developed; the upper being always stronger than the lower. The false molars are simply conical, but are more compressed than in the Carnivorous Marsupials. The posterior false molar is the largest in the upper jaw; the middle one is the largest in the lower jaw; the anterior one is the smallest in both jaws. The true molars are beset with sharp cusps which wear down into tubercles as the animal advances in age. The crowns of the upper molars present a triangular horizontal section: the base of the triangle is turned forward in the posterior molar; and obliquely inwards and outwards in the rest. In the lower jaw the true molars are narrower and of more equal size than in the upper jaw: there are five tubercles on each, four placed in two transverse pairs, the anterior being the highest, and a fifth forming the anterior and internal angle of the tooth: the anterior and external angle seems as if it were vertically cut off.

The smaller species of *Didelphis*, which are the most numerous, fulfil in South America the office of the insectivorous Shrews of the old Continent. Their external resemblance is so close that some have been described as species of *Sorex*, but no true representative of this placental genus has hitherto been discovered in South America. The larger Opossums resemble in their habits, as in their dentition, the Carnivorous *Dasyures*, and prey upon the smaller quadrupeds and birds, but they have a more omnivorous diet, feeding on reptiles and insects and even fruit. One large species, (*Did. cancrivora*) prowls about the sea-shore and lives, as its name implies, on crabs and other crustaceous animals. Another species, the Yapock, frequents the fresh waters, and preys almost exclusively on fish. It has all the habits of an Otter; and, in consequence of the modifications of its feet, forms the type of the sub-genus *Cheironectes*, Ill. Besides being web-footed the anterior extremities present an unusual development of the pisiform bone, which supports a fold of the skin, like a sixth digit; it has indeed been described, as such, by M. Temminck: this process has not, of course, any nail. The dentition of the Yapock resembles that of the ordinary *Didelphis*. All the Opossums have the inner digit of the hind foot converted by its position and development into a thumb, but without a claw. The hinder hand is associated in almost all the species with a scaly prehensile tail.

In some of the smaller Opossums the sub-abdominal tegumentary folds are rudimental, or merely serve to conceal the nipples, and are not developed into a pouch: the young in these species adhere to the mother by entwining their little prehensile tails around her's; and they cling to the fur of the back, hence the term *dorsigera* applied to one of these Opossums.*

Tribe III. *CARPOPHAGA.*

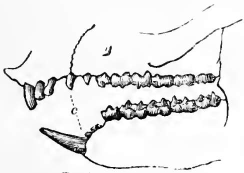
Stomach simple; cœcum very long.

In this family the teeth, especially those at the anterior part of the mouth, present considerable deviations from the previously described formulæ; the chief of which is a predominating size of the two anterior incisors, both in the upper and lower jaws. Hitherto we have seen that the dentition in every marsupial genus has participated more or less in a carnivorous character; henceforth it will manifest a tendency to the Rodent type.

Genus PHALANGISTA.

The Phalangers, so called from the phalanges of the second and third digits of the hinder extremity being inclosed in a common sheath of integument, have the innermost digit modified to answer the purposes of a thumb; and this hinder hand being associated in many of the species with a prehensile tail, they evidently, of all Frugivora, come nearest to the arboreal species of the preceding section. In a system framed on locomotive characters they would rank in the same section with the Opossums. We shall see, however, that they differ from those Entomophagous Marsupials in the condition of the intestinal tube. Let us examine to what extent the dental characters deviate from those of the Opossums.

Fig. 86.



Phalangista Cookii.

In the skull of a *Phalangista Cookii*, of which the dental formula is accurately given in *fig.* 86, there are both in the upper and lower jaws four true molars on each side, each beset with four three-sided pyramidal sharp-pointed cusps; thus these essential and most constant teeth correspond in number with those of the Opossum: but in the upper jaw they differ in the absence of the internal cusp, which gives a triangular figure to the grinding surface of the molars in the Opossum; and the anterior single cusp is wanting in the true molars of the lower jaw. Anterior to the upper grinders in this Phalanger there are two premolars of similar shape and proportions to those in the Opossum; then a third premolar, too small to be of much functional importance, separated also, like the corresponding anterior premolar in the Opossum, by a short interval from those behind.

The canine tooth but slightly exceeds in size the above false molar, and consequently here occurs the first great difference between the Phalangers and Opossums; it is, however, but a difference in degree of development; and in the Ursine and other Phalangers, as well as in the *Petaurists*, the corresponding tooth presents more of the proportions and form of a true canine.

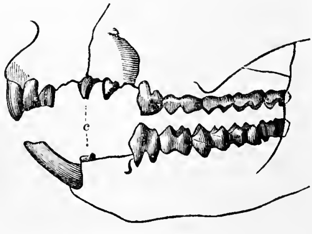
The incisors, which we have seen to be most variable in number in the Carnivorous section, are here three instead of five on each side of the upper jaw, but their size, especially that of the first, compensates for their fewness.

In the lower jaw there is the same number of molars and functional premolars as in the Opossums; the two very minute and functionless molars, which form part of the same continuous series, represent the small premolar and canine of the upper jaw; and anterior to these there is one very small and one very large and procumbent incisor on each side. Now if this comparison be just and natural, the difference in the number of teeth between the Phalanger and the Opossum will resolve itself into the former being minus certain incisors in the upper and lower jaws: in the latter, the great development of the middle incisors seems to produce an atrophy of all the rest.

The interspace between the functionally developed incisors and molars in both jaws always contains in the Phalangers teeth of small size and little functional importance, and variable not only in their proportions but their number.

The constant teeth in the Phalangers are the $\frac{4-4}{4-4}$ true molars, and the $\frac{3-3}{1-1}$ incisors.

Fig. 87.



Phalangista Vulpina.

* Few facts would be more interesting in the present branch of zoology than the condition of the new-born young, and their degree and mode of uterine development in these Opossums. Since the marsupial bones serve, not as is usually described to support a pouch, but to aid in the function of the mammary glands and testes, they of course are present in the skeleton of these small pouchless Opossums as in the more typical Marsupials.

The canines (*c. fig.* 86 and 87,) are constant in regard to their presence, but variable in size; they are always very small in the lower jaw.

With respect to the functional premolars $\frac{1-1}{1-1}$, these are always in contact with the molars, and their crowns reach to the same grinding level; sometimes a second premolar is similarly developed in the upper jaw, as in the *Phal. Cookii,* and as in the great flying Phalangers, (*Petaurus Taguanoides, fig.* 88) but it is commonly absent, or replaced by a very minute tooth, shaped like a canine; so that in the upper jaw, between the posterior or functional premolar and the incisors, we may find three teeth, of which the posterior is the largest, as in *Phal. Cookii,* or the smallest as in *Phal. cavifrons;* or there may be only two teeth as in *Phal. ursina* and *Phal. vulpina,* and the species, whatever that may be, which M. Fr. Cuvier has selected as the type of the dentition of the Genus.

In the lower jaw similar varieties occur in these small and unimportant teeth; *e. g.* there may be between the procumbent incisors and the posterior premolar, either three teeth as in *Phal. Cookii* and *Phal. cavifrons,* or two, as in *Phal. ursina, Phal. maculata, Phal. chrysorrhoos;* or finally one, as in *Phal. vulpina* and *Phal. fuliginosa.* The most important modification is presented by the little *Phal. gliriformis* of Bell, which has only three true molars on each side of each jaw. As these modifications of the teeth are unaccompanied by any change of general structure or of habit, whilst those teeth which most influence the diet are constant, it is obvious that these differences of dentition are unimportant, and afford no just grounds for subgeneric distinctions.

The Phalangers, being provided with hinder hands and prehensile tails, are strictly arboreal animals, and have a close external resemblance to the Opossums, by which name they are generally known in Australia and the Islands of the Indian Archipelago, where alone they have hitherto been found. They differ from the Opossums chiefly in their dentition; and in accordance with this difference their diet is more decidedly of a vegetable kind.* The Australian Phalangers feed chiefly on the tender buds and the leaves of *Eucalypti:* but according to Temminck,† the Indian Phalangers are omnivorous, and combine insects with fruits and leaves. Mr. Ogilby‡ states that both "the *Phalangers* and *Petaurists* display so decided a preference for live birds, as to make it probable that these constitute a main portion of their food in a state of nature." I find, however, that the intestinal canal, and especially the cœcum, offers so great an additional development in length, as, with the corresponding predominance of the incisors, and atrophy of the canines, to indicate clearly a natural and constant tendency in the Phalangers to a vegetable diet. Guided therefore by the totality of their organization, I am led to place them in a distinct section from that which contains the Opossums, but, in that section, they come the nearest to the true Opossums. The Phalangers of the Indian Isles have short ears and the greater part of the tail naked. To this group have been applied the names *Ceonyx, Cuscus,* and *Balantia;* the Australasian Phalangers have moderately long ears, and the greater part, or else the whole of the tail is covered with hair. All the species possess considerable freedom of lateral movement in the anterior digits, and in some small species, as *Phal. gliriformis,* Bell, they appear to be naturally divided into two groups, the two outer being opposed to the three inner fingers. To the hairy-tailed Phalangers exhibiting this character, Mr. Ogilby gives the subgeneric name *Pseudocheirus,* restricting the term *Phalangista* to the remaining species. With reference to the subgenera *Cuscus, Balantia, Pseudocheirus,* &c. I heartily concur in the opinion of the experienced and judicious Temminck,* that these numerous sections are perfectly useless, and a burthensome charge to the memory.

* In the stomach and intestines of specimens sent to me in spirits from Australia, I have never found any other alimentary substances but those of a vegetable nature.

† Monographies de Mammalogie, p. 3.

‡ Mag. Hist. Nat. 1837, p. 458.

Genus PETAURUS.

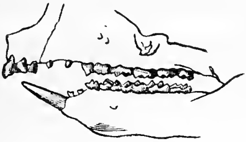
There are many species of Marsupialia limited to Australia and closely resembling, or identical with, the true Phalangers in their dental characters and the structure of the feet. I allude to the Petaurists or Flying Opossums: these, however, present an external character so easily recognizable, and influencing so materially the locomotive faculties, as to claim for it more consideration than the modifications of the digits or spurious molars which we have just been considering in the *Phalangers.* A fold of the skin is extended on each side of the body between the fore and hind legs, which, when outstretched, forms a lateral wing or parachute; but which, when the legs are in the position for ordinary support or progression, is drawn close to the side of the animal by the elasticity of the subcutaneous cellular membrane, and there forms a mere tegumentary ridge. These delicate and beautiful Marsupials have been separated generically from the Phalangers under the name of *Petaurus:* they further differ from the Phalangers in wanting the prehensile character of the tail, which, in some species of *Petaurus,* has a general clothing of long and soft hairs, whilst in others the hairs are arranged in two lateral series.

Now in the Petaurists there is as little constancy in the exact formula of the dentition as among the Phalangers. The largest species of Petaurus (*Pet. Taguanoides*) for example, is almost identical in this respect with the *Phalangista Cookii,* which M. Fr. Cuvier has therefore classed with the *Petauri.* Those teeth of *Pet. Taguanoides* which are sufficiently developed, and so equal in length, as to exercise the function of grinders, or in other words, the functional series of molars, includes six teeth on each side of the upper jaw, and five

* Loc. cit. p. 10.

teeth on each side of the lower jaw. The four posterior molars in each row are true, and bear four pyramidal cusps, excepting the last tooth in the upper jaw, which, as in *Ph. Cookii*, has only three cusps. In the upper jaw the space between the functional false molars and the incisors is occupied by two simple rudimentary teeth, the anterior representing the canine; but being relatively smaller than in *Ph. Cookii*, the crowns of the two anterior incisors are relatively larger. In the lower jaw the sloping alveolar surface between the functional molars and large procumbent incisors is occupied, according to M. Fr. Cuvier, by two rudimentary minute teeth, as represented in the figure (*fig.* 88). I have not found any trace of these

Fig. 88.



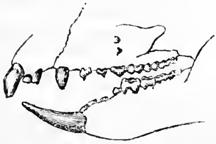
Petaurus Taguanoides.

in the two skulls of *Pet. Taguanoides* examined by me. In *Ph. Cookii* we have seen that there are three minute teeth in the corresponding space; but these differences would not be sufficient ground to separate generically the two species if they were unaccompanied by modifications of other parts of the body.

In *Petaurus sciureus* and *Petaurus flaviventer* the dentition more nearly resembles that of *Phalangista vulpina*. In the upper jaw the functional molar series consists of five teeth on each side; the four hinder ones being, as in *Pet. Taguanoides*, true tuberculate molars, but diminishing more rapidly in size as they are placed further back in the jaw; the hinder tooth has three tubercles, the rest four; the apices seem to be naturally blunter than in *Pet. Taguanoides*.

Between the functional præmolar and the incisors there are three teeth, of which the

Fig. 89.



Petaurus flaviventer.

representative of the canine is relatively much larger than in the *Pet. Taguanoides;* the first false molar is also larger and has two roots; the second, which is functional in *Pet. Taguanoides*, is here very small. The canine is more developed; the first incisor is also relatively larger and more produced. In the lower jaw the functional series of grinders consists of the four true tuberculate molars only, of which the last is relatively smaller, and the first of a more triangular form than in *Pet. Taguanoides.* The space between the tuberculate molars and the procumbent incisor is occupied by four small teeth, of which the one immediately anterior to the molars is large, compressed, pointed, and has two roots; the remaining three are rudimentary and have a single fang; the anterior of these corresponds to the one regarded as canine in the upper jaw.

Among the species exhibiting this dental formula, viz.

Incisors $\frac{3-3}{1-1}$; canines $\frac{1-1}{1-1}$; premolars $\frac{3-3}{3-3}$; molars $\frac{4-4}{4-4} = 40$,

are *Pet. sciureus, Pet. flaviventer*, and *Pet. macrurus.*

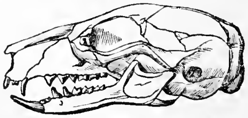
The *Pigmy Petaurist* differs from the preceding and larger species, in having the hairs of the tail distichous, or arranged in two regular lateral series like the barbs of a feather, and in having the spurious molars large and sharp-pointed; and the true molars bristled each with four acute cusps. This tendency in the dentition to the insectivorous character, with the modification of the tail, induced M. Desmarest to separate the Pigmy Petaurist from the rest of the species, and constitute a new sub-genus for its reception under the name of *Acrobates.**

To Mr. Waterhouse, however, is due the credit of having first pointed out that the Pigmy Petaurist had but three true molars on each side of each jaw instead of four. There seems, therefore, to be better reason for accepting this subgeneric section, although we evidently perceive a transition to this condition in the small size of the hinder or fourth molars in the Sciurine Petaurist and its congeners.

The description of the dentition of the Pigmy Petaurist in the Règne Animal, besides being defective in this remarkable particular, is not quite exact in other respects. In four adult specimens, two of which were males, and two females with young in the pouch, I find the following dental formula to be constant (*fig.* 90).

Incisors $\frac{3-3}{3-3}$; canines $\frac{1-1}{1-1}$; premolars $\frac{3-3}{3-3}$; molars $\frac{3-3}{3-3}$: 36.

Fig. 90.



Petaurus pigmæus, twice the natural size.

The three quadricuspidate grinders of the upper jaw are preceded by three large premolars, each of which has two fangs, and a compressed triangular sharp-pointed crown, slightly but pro-

* Ακρος, *summus*, βαινω, *gradior*, as frequenting the summits of trees.

gressively increasing in length as they are placed forward. An interspace occurs between these and the canine, which is long, slender, sharp-pointed, and recurved. The first incisor is longer than the two behind, but is much shorter than the canine. In the lower jaw the true molars are preceded by two functional false ones, similar in size and shape to the three above the anterior false molar, and the canine are represented by minute rudimental simple teeth; the single incisor is long and procumbent as in the other Petaurists.

With these differences of dentition approaching more or less to one or other of the modifications of the dentition in the group of Phalangers, the Petaurists may nevertheless be readily discriminated from those Phalangers which they most resemble; for example, the *Petaurus Taguanoides* may be distinguished from the *Phalangista Cookii* by the greater relative length in the latter of the nasal and maxillary portion of the skull; while in most of the other species of *Petaurus*, the facial part of the skull is relatively shorter than in the *Pet. Taguanoides.*

Genus PHASCOLARCTUS.

The absence of anomalous or functionless premolars and of inferior canines appears to be constant in the only known species of this genus. The dental formula in three examples of this species (*Phasc. fuscus*, Desm.) is

$$\text{Incisors } \frac{3-3}{1-1};\ \text{canines } \frac{1-1}{0-0};\ \text{premolars } \frac{1-1}{1-1};\ \text{molars } \frac{4-4}{4-4}: = 30.$$ (*Fig.* 95.)

The true molars are larger in proportion than in the Phalangers; each is beset with four three-sided pyramids, the cusps of which wear down in age, the outer series in the upper teeth being the first to give way; those of the lower jaw are narrower than those of the upper. The spurious molars are compressed and terminate in a cutting edge; in those of the upper jaw there is a small parallel ridge along the inner side of the base. The canines slightly exceed in size the posterior incisors; they terminate in an oblique cutting edge rather than a point; their fang is closed at the extremity: they are situated as in the Phalangers close to the intermaxillary suture. The lateral incisors of the upper jaw are small and obtuse; the two anterior or middle incisors are twice as long, broad, and thick as the posterior incisors; they are conical, slightly curved, sub-compressed, bevelled off obliquely to an anterior cutting edge, but differing essentially from the *dentes scalprarii* of the *Rodentia* in being closed at the extremity of the fang. The two incisors of the lower jaw resemble those of the upper, but are larger and more compressed; they are also formed by a temporary pulp, and its absorption is accompanied by a closure of the aperture of the pulp cavity, as in the upper incisors. The Koala, therefore, in regard to the number, kind, and conformation of its teeth, closely resembles the Phalangers, with which it also agrees in its long cœcum and the general conformation of its digestive organs. It has also the extremities similarly organised for prehension; each is terminated by five digits; the hind feet are provided with a large thumb, and have the two contiguous digits enveloped in the same tegumentary fold; the anterior digits are divided into two groups; the thumb and index being opposed to the other three fingers. We have already noticed a structure approaching to this in some of the small Phalangers. The Koala, however, differs from the Phalangers and Petaurists in the extreme shortness of its tail, and in its more compact and heavy general form. It is only known to feed on the buds and leaves of the trees in which it habitually resides.

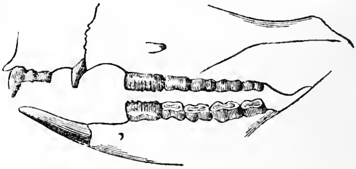
Tribe IV. *POEPHAGA.*

The present tribe includes the most strictly vegetable feeders; all the species have a complex sacculated stomach, and a long simple cœcum.

Genus HYPSIPRYMNUS. Potoroos.

Guided by the modifications of the teeth we pass from the Koala to the Potoroos and Kangaroos—animals of widely different general form. The Potoroos, however, present

Fig. 91.



Hypsiprymnus murinus.

absolutely the same dentition as does the Koala, some slight modifications in the form of certain teeth excepted. The premolars in their longitudinal extent, compressed form, and cutting edge, would chiefly distinguish the dentition of the *Potoroo;* but the Koala evidently offers the transitional structure between the Phalangers and Potoroos in the condition of these teeth, of which one only is retained on each side of each jaw in the Potoroos as in the Koala.

The dental formula of *Hypsiprymnus*, the generic name of the Potoroos, is

$$\text{Incisors } \frac{3-3}{1-1};\ \text{canines } \frac{1-1}{0-0};\ \text{premolars } \frac{1-1}{1-1};\ \text{molars } \frac{4-4}{4-4}: = 30.$$

The two anterior incisors are longer and more curved, the lateral incisors relatively smaller than in the Koala. The pulps of the anterior incisors are persistent. The canines are larger than in the Koala; they always project from the line of the intermaxillary suture; and, while the fang is lodged in the maxillary bone, the crown projects almost wholly from the intermaxillary. In the large *Hypsiprymnus ursinus* the canines are relatively smaller than in the other Potoroos, a structure which indicates the transition from the Potoroo to the Kangaroo genus. In the skeleton of this species in the

Leyden Museum, the canines have a longitudinal groove on the outer side.

The characteristic form of the trenchant premolar has just been alluded to: its maximum of development is attained in the arboreal Potoroos of New Guinea (*Hypsiprymnus ursinus* and *Hyps. dorcocephalus*), in the latter of which its antero-posterior extent nearly equals that of the three succeeding molar teeth. In all the Potoroos the trenchant spurious molar is sculptured, especially on the outer side, and in young teeth, by many small vertical grooves. The true molars each present four three-sided pyramidal cusps; but the internal angles of the two opposite cusps are continued into each other across the tooth, forming two angular or concave transverse ridges. In the old animal these cusps and ridges disappear, and the grinding surface is worn quite flat, as in *fig.* 91, which represents the dentition of the original Potoroo, described in White's Voyage.

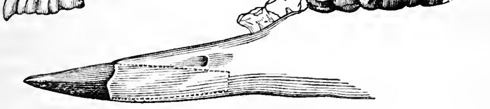
Genus MACROPUS. Kangaroos.

In the genus *Macropus* (*fig.* 92) the normal condition of the permanent teeth may be expressed as follows:—

Incisors, $\frac{3-3}{1-1}$; canines, $\frac{0-0}{0-0}$; premolars, $\frac{1-1}{1-1}$; molars, $\frac{4-4}{4-4} = 28$.

The main difference, as compared with *Hypsiprymnus*, lies in the absence of the upper canines as functional teeth; the germs, however, of these teeth are always to be found in the young mammary fœtus of the *Macropus major*, and I have seen them present, but of very small size, and concealed by the gum, in the adults of some small species of kangaroos, as *Macropus rufiventer*, Ogilby, and *Macr. psilopus*, Gould. This, however, is a rare exception; while the constant presence and conspicuous size of the canines will always serve to distinguish the Potoroo from the Kangaroo. But there are also other differences in the form and proportions of certain teeth. The upper incisors of the *Macropi* have their cutting margins in the same line, the anterior ones not being produced beyond that line, as in the *Hypsiprymni*: the third or external incisor is also broader in the kangaroos, and is grooved and complicated by one or two folds of the enamel, continued from the outer side of the tooth obliquely forward and inward. In most species the anterior fold is represented by a simple groove: the relative size of the outer incisor, the extent and position of the posterior fold of enamel, and consequently the proportions of the part of the tooth in front or behind it, vary more or less in every species of Macropus: there are two folds of enamel near the anterior part of the tooth in *Macr. major*, and the posterior portion is of the greatest extent, and the entire crown of the tooth is relatively broadest in this species. The middle incisor is here also complicated by a posterior notch and an external groove. These modifications of the external incisors of the kangaroos were first noticed by Mr. Jourdan, and subgeneric distinctions, with names often sufficiently unmeaning, if not absurd,* have been subsequently based upon them; but such dental characters possess neither sufficient constancy nor physiological importance to justify such an application.

Fig. 92.



Macropus major, one-third nat. size.

M. Fr. Cuvier has proposed a binary division of the genus *Macropus*, as here defined, founded on the absence of permanent spurious molars, and a supposed difference in the mode of succession of the true molars in certain species of *Kangaroo*, combined with modifications of the muzzle or upper lip, and of the tail.

The dental formula which I have assigned to the genus *Macropus* is restricted in its application by that naturalist to some small species of *Kangaroo*, grouped together under the term *Halmaturus*, originally applied by Illiger to the *Kangaroos* generally.† The rest of the *Kangaroos*, under the generic term *Macropus*, are characterised by the following dental formula:—Incisors, $\frac{6}{2}$; molars, $\frac{4-4}{4-4} = 24$.

The truth, however, is, that both the *Halmaturi* and *Macropi* of M. Fr. Cuvier have their teeth developed in precisely the same number and manner: they only differ in the length of time during which certain of these teeth are retained.‡ In the great *Kangaroo*, for example, the permanent premolar which suceeeds the corresponding deciduous one in the vertical direction, is pushed out of place and shed by the time the last

* E. g. *Bettongia*, Gray, *Petrogale*, Gray, which signifies 'rock weasel.'

† *Prodromus Systematis Mammalium et Avium*, 8vo. 1811. The dental character which this excellent naturalist gives, accurately expresses the condition of the canine or laniary teeth, "Laniarii aut nulli, aut superiores 2 ambigui, minuti, in medio inter primores et molares collocati," p. 80; but there are never more than five molars in place on each side of each jaw in the Kangaroo.

‡ M. Fr. Cuvier was aware that a deciduous spurious molar existed in the great *Kangaroo* and other species of his subgenus Macropus, but he believed that it was peculiar to an early period of life, and then existed only in a rudimental state, or "en germe," and that instead of being displaced and

true molar has cut the gum: the succeeding true molar is soon afterwards extruded; and I have seen a skull of an old *Macropus major* in the Museum at Leyden, in which the grinders were reduced to two on each side of each jaw by this yielding of the anterior ones to the vis a tergo of their successors.

The general form of the body in the *Macropodidæ* is that of an elongated cone, the broad and stout haunches forming the base, and the produced tapering muzzle the apex. The proportions of the body are, however, reduced by so elegant a gradation that they are justly considered as among the most picturesque of quadrupeds. The hinder extremities are always longer and stronger than the fore ones, but in various proportions; the difference being least in the arboreal Potoroos, and in that section of the genus represented by the *Hypsiprymnus myosurus* of Van Dieman's Land. The tail is very long in all the species, but is strongest in the great kangaroos, which make use of it as a kind of crutch or fifth extremity in their slower modes of progression. In the Potoroos the tail is more slender, and in these and some of the smaller species of kangaroo it is bent beneath the body when the animal reposes.

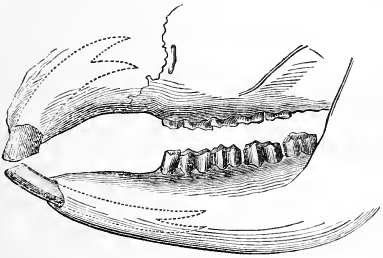
Tribe V. *RHIZOPHAGA.*

In this tribe, the stomach is simple in outward form, but complicated within by a large cardiac gland; and the cœcum, which is short and wide, with a vermiform appendage.

Genus PHASCOLOMYS, (*fig.* 93.)

In its heavy shapeless figure, large trunk, and short equably developed legs, the Wombat offers as great a contrast to the Kangaroos as

Fig. 93.



Phascolomys fusca, Geoff. one-half nat. size.

does the Koala, which it most nearly resembles in its general outward form and want of tail. But in the more important characters afforded by the teeth and intestinal canal, the Wombat differs more from the Koala than the latter does from either the Phalangers or Kangaroos.

The dental system presents the extreme degree of that degradation of the teeth, intermediate between the front incisors and true molars, which we have been tracing from the Opossum to the Kangaroos: not only have the functionless premolars and canines now totally disappeared, but also the posterior incisors of the upper jaw, which we have seen in the Potoroos to exhibit a feeble degree of development as compared with the anterior pair; these in fact are alone retained in the dentition of the present group, the representative of which possesses the fewest teeth of any Marsupial animal. The dental formula of the Wombat is thus reduced both in number and kind to that of the true Rodentia.*

Incisors, $\frac{2}{2}$; canines, $\frac{0}{0}$; premolars, $\frac{1-1}{1-1}$; molars, $\frac{4-4}{4-4} = 24.$

The incisors moreover are true *dentes scalprarii*, with persistent pulps, but are inferior, especially in the lower jaw, in their relative length and curvature to those of the placental Glires; they present a subtriedral figure, and are traversed by a shallow groove on their mesial surfaces.

The spurious molars present no trace of that compressed structure which characterizes them in the Koala and Kangaroos, but have a wide oval transverse section; those of the upper jaw being transversed on the inner side with a slight longitudinal groove. The true molars are double the size of the premolars: the superior ones are also traversed by an internal longitudinal groove, but this is so deep and wide that it divides the whole tooth into two prismatic portions, with one of the angles directed inwards. The inferior molars are in like manner divided into two triedral portions, but the intervening groove is here external, and one of the facets of each prism is turned inwards. All the grinders are curved, and describe about a quarter of a circle: in the upper jaw the concavity of the curve is directed outwards; in the lower jaw, inwards. The false and true molars, like the incisors, have persistent pulps, and are consequently devoid of true fangs, in which respect the Wombat differs from all other Marsupials, and resembles the extinct *Toxodon*, the dentigerous *Bruta*, and herbivorous *Rodentia.*

I may add that the Wombat deviates from the other Marsupials in the number of its ribs; as these are very constant in the rest of the order, the difference in the Wombat, which has 15 pairs, instead of 13 or 12, is the more deserving

succeeded in the vertical direction by a permanent spurious molar, as in the *Halmaturi*, it was displaced by the true molars, which are developed from behind forwards. I have however detected the crown of the permanent spurious molar in the jaws of the *Macropus major* in a concealed alveolus, and have observed it completely formed and in place in an individual which had nearly attained its full size.—See F. Cuvier's account of the *Halmaturus Thetis* in the "Histoire des Mammifères," folio.

* In all the placental Rodents, which have more than three molars in each lateral series, the additional ones are placed at the anterior part of the row, and are subject to displacement by a permanent successor in the vertical direction, and consequently are essentially "premolars," or spurious molars; the Wombat strikingly manifests its marsupial character in having four true molars on each side of both jaws.

of notice. The *Koala*, like the Phalangers and Kangaroos, has 13 pairs of ribs; but this class of characters will form the subject of the following section.

Osteology of the Marsupialia.

Of the Skull.—The form of the skull varies much in different Marsupial animals, but it may be said, in general terms, to resemble an elongated cone, being terminated by a vertical plane surface behind, and in most of the species converging towards a point anteriorly: it is also generally more depressed or flattened than in the placental Mammalia. The skull is also remarkable in all the Marsupial genera for the small proportion which is devoted to the protection of the brain, and for the great expansion of the nasal cavity immediately anterior to the cranial cavity.

In the stronger carnivorous Marsupials the exterior of the cranium is characterized by bony ridges and muscular impressions, but in the smaller herbivorous and insectivorous species, as the Petaurists, Potoroos, and *Myrmecobius*, the cranium presents a smooth convex surface as in Birds, corresponding with the smooth unconvoluted surface of the simple brain contained within.

The breadth of the skull in relation to its length is greatest in the Wombat,* Ursine Dasyure† and Petaurists, in which it equals three-fourths of the length, and is least in the *Perameles lagotis*, in which it is less than one-half.

The occipital region, which is generally plane, and vertical in position, forms a right angle with the upper surface of the skull, from which it is separated by an occipital or lambdoidal crista. This crista is least developed in the Myrmecobius, Petaurists, and Kangaroos, and most so in the Thylacine and larger Opossums, in which, as also in the Koala, the crest curves slightly backwards, and thus changes the occipital plane into a concavity for the firm implantation of the strong muscles from the neck and back.

The upper surface of the skull presents great diversity of character, which relates to the different development of the temporal muscles, and the varieties of dentition in the different genera.

In the Wombat the coronal surface offers an almost flattened tract bounded by two slightly elevated temporal ridges, which are upwards of an inch apart posteriorly, and slightly diverge, as they extend forwards to the anterior part of the orbit.

The skull of the Virginian Opossum presents the greatest contrast to that condition, for the sides of the cranium meet above at an acute angle, and send upwards from the line of their union a remarkably elevated sagittal crest, which, in mature skulls, is proportionally more developed than in any of the placental Carnivora, not even excepting the strong-jawed Hyæna.

The Thylacine and Dasyures, especially the Ursine Dasyure, exhibit the sagittal crest in a somewhat less degree of development. It is again smaller, but yet well marked in the Koala and Perameles. The temporal ridges meet at the lambdoidal suture in the larger *Phalangistæ* and in the *Hypsiprymni*, but the size of the muscles in these does not require the development of a bony crest.

In the Kangaroo, the temporal ridges, which are very slightly raised, are separated by an interspace of the third of an inch.

They are separated for a proportionally greater extent in the Petaurists, especially *Petaurus flaviventer*; and in the smooth and convex upper surface of the skull of *Petaurus sciureus*, *Pet. pigmæus*, *Myrmecobius*, the impressions of the feeble temporal muscles almost cease to be discernible.

The zygomatic arches are, however, complete in these as in all the other genera: they are usually, indeed, strongly developed; but their variations do not indicate the nature of the food so clearly, or correspond with the differences of animal and vegetable diet in the same degree as in the placental Mammalia. And this is not surprising when we recollect that no Marsupial animal is devoid of incisors in the upper jaw, like the ordinary Ruminants of the placental series: accordingly the more complete dental system with which the herbivorous Kangaroos, Potoroos, Phalangers, &c. are provided, and which appears to be in relation to the scantier pasturage and the dry and rigid character of the herbage or foliage on which they browse, requires a stronger apparatus of bone and muscle for the action of the jaws, and especially for the working of the terminal teeth. There are, however, well marked differences in this part of the Marsupial skull; and the weakest zygomatic arches are those of the Insectivorous *Perameles* and *Acrobates*, in which structure we may discern a correspondence with the Edentate Anteaters of the placental series. Still the difference in the development of the zygomata is greatly in favour of the Marsupial Insectivora.

The *Hypsiprymni* come next in the order of development of the zygomatic arches; which again are proportionally much stronger in the true Kangaroos. The length of the zygomata in relation to the entire skull is greatest in the Koala and Wombat. In the former animal they are remarkable for their depth and straight and parallel course, as well as for their longitudinal extent. In the Wombat they have a considerable curve outwards, so as greatly to diminish the resemblance which otherwise exists in the form of the skull between this Marsupial and the Herbivorous Rodentia of the placental series, as, *e. g.* the Viscaccia.

In the carnivorous Marsupials the outward sweep of the zygomatic arch, which is greatest in the Thylacine und Ursine Dasyure, is also accompanied by a slight curve upwards, but this curvature is chiefly expressed by the concavity of the lower margin of the zygoma, and is by no means so well marked as in the placental Carnivora. It is remarkable that this upward curvature is greater in the slender zygomata of the Perameles than in the stronger zygomata of the Dasyures and Opossums. In the Koala and Phalangers there is also a slight tendency to the upward curvature; in the

* As 15 to 20. † As 10 to 14.

Wombat the outwardly expanded arch is perfectly horizontal. In the Kangaroo the lower margin of the zygoma describes a slightly undulating curve, the middle part of which is convex downwards.

In many of the Marsupials, as the Kangaroo, the Koala, some of the Phalangers, Petaurists, and Opossums, the superior margin of the zygoma begins immediately to rise above the posterior origin of the arch. In the Wombat an external ridge of bone commences at the middle of the lower margin of the zygoma, and gradually extends outwards as it advances forwards, and being joined by the upper margin of the zygoma, forms the lower boundary of the orbit, and ultimately curves downwards in front of the ant-orbital foramen, below which it bifurcates and is lost. This ridge results, as it were, from the flattening of the anterior part of the zygoma, which thus forms a smooth and slightly concave horizontal platform for the eye to rest upon.

The same structure obtains, but in a slighter degree, in the Koala.

In the Kangaroo the anterior and inferior part of the zygoma is extended downwards in the form of a conical process, which reaches below the level of the grinding-teeth. A much shorter and more obtuse process is observable in the corresponding situation in the Phalangers and Opossums.

The relative length of the facial part of the skull anterior to the zygomatic arches varies remarkably in the different Marsupial genera. In the Wombat it is as six to nineteen; in the Koala as five to fourteen; in the *Petaurus sciureus* and *Petaurus Bennettii* it forms about one-fourth of the entire skull; in the Phalangers about one-third; in the carnivorous Dasyures and Opossums more than one-third; in the Thylacine nearly one-half; in Perameles, Macropus, and *Hypsiprymnus murinus*, Ill. the length of the skull anterior to the orbit is equal to the remaining posterior part; but in a species of Hypsiprymnus from Van Dieman's Land (*Hypsiprymnus myosurus*, Ogilb.), the facial part of the skull anterior to the orbit exceeds that of the remainder, and the arboreal *Hypsiprymni* from New Guinea present a still greater length of muzzle. In most Marsupials the skull gradually converges towards the anterior extremity; the convergence is more sudden in the *Petaurists*, especially *Pet. Bennettii;* but in the *Perameles lagotis* the skull is remarkable for the sudden narrowing of the face anterior to the orbits, and the prolongation of the attenuated snout, preserving the same diameter for upwards of an inch before it finally tapers to the extremity of the nose. In the Koala the corresponding part of the skull is as remarkable for its shortness, as it is in the *Per. lagotis* for its length, but it is bounded laterally by parallel lines through its whole extent. Before concluding this account of the general form of the skull, I may observe that in nearly all the Marsupials two long processes project downwards from the inferior angles of the occipital region; they correspond in function with, and have been described as the mastoids, but they are developed from the ex-occipital bones. These processes are longest in the Kangaroos and Koala; in the Wombat they co-exist with the true mastoid processes, which are of larger size. In the Opossums and Dasyures the exoccipital processes are short and obtuse; in *Acrobates* they cease to exist, but they are present in the larger *Petaurists.*

Of the composition of the cranium.—The *occipital bone* is developed, as in the placental Mammalia, from four centres or elements,—the basilar below, the supra-occipital above, and the ex-occipitals at the sides; but these elements remain longer separate, and in some genera do not become at any period of life united by continuous ossification.

In the skull of an aged Virginian Opossum, I found the supra-occipital still distinct from the ex-occipitals, and these not joined together, though anchylosed to the basilar element. I say not joined together, because in this Marsupial animal they meet above the foramen occipitale and complete its boundaries, as the corresponding superior vertebral laminæ complete the medullary canal in the region of the spine. I find the same structure and condition of the occipital bone of an adult *Dasyurus Ursinus*, and it is exhibited in the plate of the cranium of this species given by M. Temminck.*

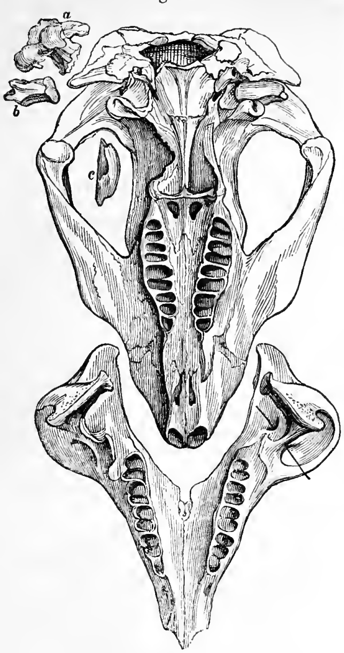
In the skull of the mature Wombat, of which a reduced representation is given at *fig.* 94, the ex-occipitals were still unanchylosed; the left is figured separate at *a.*

In the skull of a *Perameles nasuta* the ex-occipitals are separated by an interspace, so that a fissure is continued from the upper part of the foramen magnum to the supra-occipital element. The same structure may be observed in the great Kangaroo, and it is very remarkable in the young skulls of this species; I found this superior notch wide and well marked in *Macropus Bennettii.* In the Wombat the corresponding fissure is very wide, and the lower margin of the supra-occipital is notched, so that the shape of the foramen magnum somewhat resembles that of the trefoil leaf. In the Koala, the Phalanger, Petaurists, Hypsiprymni, and Dasyurus Maugei, the elements of the occipital bone present the usual state of bony confluence.

The *temporal bone* generally presents a permanent separation of the squamous, petrous, and tympanic elements. I have observed this reptilian-like condition of the bone in the mature skulls of an Ursine Dasyure, a Virginian Opossum, a Perameles, in different species of Potoroo and Kangaroo, in the Wombat, and in the Koala. The petrous and mastoid elements are commonly anchylosed together. So loose indeed is the connexion of the tympanic bone, that without due care it is very liable to be lost in preparing the skulls of the Marsupials. In the Kangaroo and Wombat (*fig.* 94, *b*) it

* Monographies de Mammalogie, pl. viii.

Fig. 94.



Phascolomys.

forms a complete bony tube, about half an inch in length, with an irregular exterior; it is wedged in between the mastoid and articular processes of the temporal bone. In the Potoroo the bony circle is incomplete at the upper part; in the Perameles and Dasyures the tympanic bone forms a semicircle, the posterior part being deficient, and the tympanic membrane being there attached to a descending process of the squamous element of the temporal bone. Here we have a near approach to the form of tympanic bone in Birds, but we have a still closer resemblance to its condition both in Birds and Reptiles, in its want of union with and relations to the petrous element of the temporal bone. In the Rodent quadrupeds the tympanic, petrous, and mastoid elements of the temporal bone are always anchylosed together; this condition is well shown in the skull of the Porcupine and Beaver, in which the mastoid element sends down a thin obtuse process behind the petro-tympanic portion. It is to the expansion of the petro-tympanic, and not of the mastoid portion of the temporal bone, that the enlargement of the tympanic cavity is due in the Rodentia, and this expansion forms in that order, as is well known, a large *bulla ossea*, which is situated anterior and internal to the mastoid process. In many of the Marsupials, as the Dasyures, Petaurists, Perameles, Potoroos, and Koala, there is also a large *bulla ossea* for the purpose of increasing the extent of the auditory cavity; but, with one single exception, the Wombat, this *bulla* is not formed by the tympanic or any other element of the temporal bone, but by the expansion of the base of the great ala of the sphenoid bone. In *Acrobates* and *Perameles lagotis*, in addition to the preceding bulla there is also an external dilatation of the petrous element of the temporal bone, which thus forms a second and smaller bulla on each side, behind the large bulla ossea formed by the sphenoid. In other Marsupials the petrous bone is of small size, generally limited to the office of protecting the parts of the internal ear, and sometimes, as in the Koala, is barely visible at the exterior of the base of the skull. The petrous and mastoid elements are usually anchylosed together in the Marsupials, and the mastoid portion appears in the occipital region of the skull of the Koala, between the ex-occipital bones and squamous portion of the temporal. The petrous element of the temporal bone appears externally in the corresponding part of the skull of a young Emeu. In the Kangaroos and Wombat the petro-mastoid bone presents a larger size, and is visible in two situations on the outside of the skull, viz. at the usual place at the basis, where the petrous portion is wedged in between the basilar bone, ex-occipital and sphenoid, and again at the side of the cranium, where the mastoid portion appears between the squamous, ex-occipital, and supra-occipital bones. In the Wombat it sends outwards the strong compressed process which terminates the lateral boundaries of the occipital plane of the cranium; but this process is entirely due to the ex-occipitals in the Koala and other Marsupials.

The auditory chamber of the ear is augmented in the Phalangers, the Koala, the Kangaroos, and Potoroo, by a continuation of air-cells into the base or origin of the zygomatic process; but the extent of the bony air-chambers communicating with the tympanum is proportionally greatest in the Flying Opossums, where, besides the sphenoid bulla, the mastoid element and the whole of the zygomatic process of the temporal bone are expanded to form air-cells with very thin and smooth walls, thus presenting an interesting analogy in the structure of the cranium to the class of birds.

The direction of the bony canal of the organ of hearing corresponds, as in the placental Mammalia, with the habits of the species. The meatus is directed outwards and a little forwards in the carnivorous Dasyures; outwards and a little backwards in the Perameles and Phalangers; outwards, backwards, and upright in the Kangaroos, and directly outwards in the Petaurists and Wombat; but the differences of direction are but slightly marked.

The squamous element of the temporal bone generally reaches half-way from the root of the zygoma to the sagittal ridge or suture; it is most developed in the Wombat, in which its superior margin describes a remarkably straight line. The zygomatic process of the temporal bone is generally compressed and much extended in the vertical direction in the Opossum, Dasyure, Phalanger, Koala, and Kangaroo. In the Wombat it curves outwards from the side of the head in the form of a compressed and almost horizontal plate; it is then suddenly twisted into the vertical position, to be received into the notch of the malar portion of the arch.

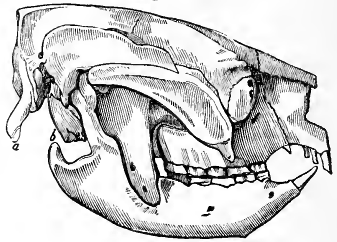
The cavity corresponding to the sphenoidal bulla ossea in other Marsupials is in this species excavated in the lower part of the squamous element of the temporal bone at the inner side of the articular surface for the lower jaw. This articular surface, situated at the base of the zygomatic process, presents in the marsupial, as in the placental Mammalia, various forms, each manifesting a physiological relation to the structure of the teeth and adapted to the required movement of the jaws in the various genera. In the herbivorous Kangaroo the glenoid cavity forms a broad and slightly convex surface, as in the Ruminants, affording freedom of rotation to the lower jaw in every direction. In the Phalangers and Potoroos the articular surface is quite plane. In the Perameles it is slightly convex from side to side, and concave from behind forwards. In the Wombat it is formed by a narrow convex ridge considerably extended, and slightly concave, in the transverse direction. This ridge is not bounded by any descending process posteriorly, so that the jaw is left free for the movements of protraction and retraction. But this structure is widely different from that which facilitates similar movements in the Rodentia. In these there is a longitudinal groove on each side, in which the condyle of the lower jaw plays backwards and forwards, but is impeded in its lateral movements; these, on the contrary, are freely allowed to the Wombat, and the oblique disposition of the lines of enamel upon the molar teeth correspond with the various movements of which the lower jaw of the Wombat is thus susceptible. In the Koala the glenoid cavity is a transversely oblong depression with a slight convex rising at the bottom, indicating rotatory movements of the jaw. In the carnivorous Dasyures it forms a concavity still more elongated transversely, less deep than in the placental Carnivora, but adapted, as in them, to a ginglymoid motion of the lower jaw. In all the genera, save in the Wombat, retraction of the lower jaw is opposed by a descending process of the temporal bone immediately anterior to the meatus auditorius and tympanic bone.

The glenoid cavity presents a characteristic structure in most of the Marsupialia in not being exclusively formed by the temporal bone. With the exception of the Petaurists, the malar bone forms the outer part of the articular surface for the lower jaw, and in the *Thylacinus*, *Dasyurus Maugei*, *Dasyurus ursinus*, *Perameles*, *Hypsiprymnus*, and *Macropus* the sphenoid ala forms the inner boundary of the same surface; but this ala does not extend so far outwards and backwards in the Wombat or Koala.

The *sphenoid bone* has the same general form and relative position as in the ordinary Mammalia, but in many Marsupials it presents a similarity to that in the Ovipara in the persistence of the pterygoid processes as separate bones, as shown in the Wombat (*fig.* 94, *c*). It is only in the Koala that I have observed a complete obliteration of the suture joining the basilar element of the sphenoid with that of the occipital bone. In the Thylacine a narrow straight bridge of bone is continued from the auditory sphenoidal bulla forwards to the base of the pterygoid process, resembling the condition of the pterygoids in Birds.

The chief peculiarity in the sphenoid bone is the dilatation of the root of the great ala already alluded to. This dilatation communicates and is filled with air from the tympanum. It forms the hemispherical bulla ossea on each side of the basis cranii in the Dasyures and Phascogales, and the large semi-ovate bullæ in the Myrmecobius, Cook's Phalanger, &c.; but in the Koala the bullæ (*b*, *fig.* 95,) are still

Fig. 95.



Phascolarctus.

more developed, and are produced downwards to an extent equal with the ex-occipital processes (*a*, *fig.* 95); they are somewhat compressed laterally, and instead of the smooth and polished surface which characterizes them in the preceding genera, terminate here in a rough ridge. The dilated air-chambers or bullæ of the sphenoid are very small in the Thylacine; in the Phalangers and Potoroos they are relatively smaller than in the Dasyures, and they are incomplete posteriorly in the Kangaroos and Wombat. In the Brush-Kangaroo the above process from the sphenoid joins the base of the large descending process of the ex-occipital. The pterygoid processes are relatively largest in the Kangaroo, Wombat, and Koala, and present in each of these species distinct hamular processes. In the Potoroo, Kangaroo, and Wombat the sphenoid ala combines with the pterygoid process to form a large and deep depression opening externally. In the Kangaroo, Dasyures, Koala, and Wombat the great alæ of the sphenoid articulate with the parietal bones, but by a very small portion in the two latter species: in the Perameles and Potoroos the sphenoid alæ do not reach the parietals.

There is little to notice in the *parietal bones* except the obliteration of the sagittal suture in those species in which a bony crista is developed in the corresponding place. They present a singularly flattened form in the Wombat, in an aged skull of which, and in a similar one in the Kangaroo, I observe a like obliteration of the sagittal suture. In the Kangaroo, Potoroo, Petaurus, Phalanger, and Myrmecobius there is a triangular inter-parietal bone. The corresponding bone I find in three pieces in the skull of a Wombat.

The *frontal bones* are chiefly remarkable for their anterior expansion and the great share which they take in the formation of the nasal cavity. In the Thylacine the part of the cranium occupied by the frontal sinuses exceeds in breadth the cerebral cavity, from which it is divided by a constriction. The coronal suture presents in most of the Marsupials an irregular angular course, forming a notch in the frontals on each side which receives a corresponding triangular process of each parietal bone: this form of the suture is least pronounced in the *Acrobates* and *Myrmecobius*. A process corresponding to the posterior frontal augments the bony boundary of the orbit in the Thylacine, the Ursine Dasyure, and in a slighter degree in the Virginian Opossum; it is relatively most developed in the skull of the *Myrmecobius fasciatus*, where the orbit is large; but the bony boundary of the orbit is not complete in any of the Marsupials. In the Myrmecobius there is a deep notch at the middle of the supra-orbital ridge. A corresponding but shallower notch is present in the skull of *Petaurus sciureus*. I have found the frontal suture obliterated in old specimens of the Thylacine, the Virginian Opossum, Cook's Phalanger, the taguanoid, and yellow-bellied Petaurists; but the frontal suture exists in *Petaurus Sciureus*, *Acrobates*, and other Marsupials. The inter-orbital space is concave in the Phalangers and in the Petaurus Taguanoides, but is quite flat in the other Petaurists.

The *lachrymal bones* vary in their relative size in different Marsupialia. In the Koala they extend upon the face about a line beyond the anterior boundary of the orbit, and at this part they present a groove with one large and two or three small perforations. In the Wombat their extent upon the face is slightly increased; it is proportionally greater in the Kangaroos, Potoroos, Phalangers, Petaurists, and Dasyures, in which this part of the lachrymal bone presents two perforations close to the orbit. In the Thylacine, besides the two external holes there is a large perforation within the orbital margin. This carnivorous Marsupial, as compared with the Wolf, presents a greater extent of the facial portion of the lachrymal bone, and thus indicates its inferior type. In the *Myrmecobius* the lachrymal bone exhibits its greatest relative development.

The *malar bones* are very strong and of great extent in almost all the Marsupialia. They are least developed in *Acrobates*, *Myrmecobius*, and *Perameles lagotis*. In the latter the malar bone presents a singular form, being bifurcate at both extremities: the *processus zygomaticus maxillæ superioris* is wedged into the cleft of the anterior fork; the corresponding process of the temporal bone fills up the posterior notch; the lower division of this bifurcation is the longest, and in all the Marsupialia enters into the composition of the articular surface for the lower jaw, except in the Petaurists, where it just falls short of this part. The anterior bifurcation of the malar bone is not present in the Marsupials generally; the external malo-maxillary suture forms an oblique and almost straight line in the Wombat, Phalanger, Opossum, Dasyures, and Kangaroo. Owing to the inferior development of the zygomatic process of the superior maxillary in the Wombat, the malar bone is not suspended in the zygomatic arch in this Marsupial as in the placental Rodentia. It is also of relatively much larger size and of a prismatic form, arising from the development of the oblique external ridge above described. In the Kangaroos, Potoroos, Great Petaurus, and Phalangers it is traversed externally by a ridge showing the extent of attachment of the masseter; in the Koala the ridge extends along the malar bone near the upper margin, and the surface below presents a well-marked excavation.

The *nasal bones* vary in their form and relative size in the different genera; they are longest and narrowest in the Perameles, shortest and broadest in the Koala. Their most characteristic structure is the expansion of their upper and posterior extremity, which is well marked in the Wombat, Myrmecobius, Petaurists, Phalangers, Opossums and Dasyures.

In the Potoroos the anterior extremities of the nasal bones converge to a point which projects beyond the inter-maxillaries. In some Petaurists and Perameles the corresponding points reach as far as the inter-maxillaries, and in a skull of the *Perameles lagotis* I have found the bony case of the nasal passages to be further increased by the presence of two small *rostral bones*, resulting, as in the Hog, from ossification of the nasal cartilage.

The *inter-maxillary bones* always contain teeth, and the ratio of the development of these bones corresponds with the bulk of the dental apparatus which they support. They are consequently largest in the Wombat, where they extend far upon the side of the face and are articulated to a considerable proportion of the nasal bones, but do not, as in the placental Rodentia, reach the frontal or divide the maxillary bone from the nasal. They present a somewhat lower degree of development in the Koala, but both in this species and in the Wombat they bulge outwards and thus remarkably increase the transverse diameter of the osseous cavity of the nose. Neither in *Hypsiprymnus* nor *Macropus* do I find the incisive palatal foramina entirely in the intermaxillary bones, as is described by the author of the text in Pander and D'Alton's

Skelete der Beutelthiere; a small proportion of their bony circumference is due to the anterior extremity of the palatal process of the maxillary: the same structure obtains in the Wombat, Koala, and Opossums. In the Dasyures and Phalangers a greater proportion of the posterior boundary of the incisive or anterior palatal foramina is formed by the maxillaries; in the Petaurists they are entirely surrounded by the maxillary bones, while in the Perameles they are, on the contrary, entirely included in the intermaxillaries. They always present the form of two longitudinal fissures: the Myrmecobius agrees with the other Marsupials in this structure.

The *superior maxillary bone* in the Wombat sends upwards a long, narrow, irregular nasal process, which joins the frontal and nasal bones, separating them from the intermaxillaries; the part of the maxillary bone which projects into the temporal fossa behind the orbit presents two or three smooth tuberosities, formed by the thin plate of bone covering the pulps of the large curved posterior grinders. The corresponding part in the *Perameles lagotis* is perforated by numerous minute apertures like a cribriform plate, and this structure is presented in a slighter degree in the Potoroos and Ursine Dasyure. The antorbital foramen does not present any marked variety of size, which is generally moderate. It is much closer to the orbit in the carnivorous Marsupialia than in the corresponding placental quadrupeds. It is relatively largest in the Ursine Dasyure. It presents the form of a vertical oblique fissure in the Wombat. I have observed it double in the Kangaroo. The chief differences in the maxillary bones, independently of the teeth and their alveoli, are presented by the palatal processes, the modifications of which we shall consider in conjunction with those presented by the palatal processes of the palatal bones. The perforations and vacuities of the bony palate deserve, indeed, particular attention, as they are often specific and of consequence in the determination both of recent and fossil species.

In *Phalangista Cookii*, in *Petaurus flaviventer*, and *Petaurus sciureus*, in *Macropus major*, and some other great Kangaroos the bony palate is of great extent and presents a smooth surface, concave in every direction towards the mouth; it is pierced by the two posterior palatine foramina at the anterior external angles of the palatine bones, either within or close to the transverse palato-maxillary sutures. Behind these foramina, in the Kangaroo, there are a few small irregular perforations. The bony palate is similarly entire in the *Hypsiprymnus ursinus*. In *Macropus Bennettii* there are four orifices at the posterior part of the bony palate. The two anterior ones are situated upon the palato-maxillary suture, and are of an ovate form with the small end forwards. The two posterior foramina are of a less regular form and smaller size. In the Brush Kangaroo (*Macropus Brunii*, Cuv.) the posterior palatal foramina present the form of two large fissures placed obliquely and converging posteriorly. They encroach upon the posterior borders of the maxillary plate. Anterior to these vacancies there are two smaller foramina, and posterior to them are one or two similar foramina.

In the Australian Potoroos, Wombat, and Koala, the posterior palatal openings are large and oval, and situated entirely in the palatal bones. In *Hyps. setosus* they extend as far forwards as the interspace between the first and second true molars; in *Hyps. murinus* they reach to that between the second and third true molars. Posterior and external to these large vacuities there are two small perforations. In the Phalangers, with the exception of *Ph. Cookii*, the palatal openings are proportionally larger; they extend into the palatal process of the maxillaries, and the thin bridge of bone which divides the openings in the Potoroo, &c., is wanting; the two perforations at the posterior external angles of the palatine bones are also present. In the Virginian Opossum the bony palate presents eight distinct perforations, besides the incisive foramina; the palatal processes of the palatine bone extend as far forwards in the median line as the third molars: a long and narrow fissure extends for an equal distance (three lines) into the palatal processes both of the palatines and maxillaries: behind these fissures and nearer the median line are two smaller oblong fissures; external and a little posterior to these are two similar fissures, situated in the palato-maxillary suture; lastly, there are two round perforations close to the posterior margin of the bony palate.

In the Ursine Dasyure a large transversely oblong aperture is situated at the posterior part of the palatal processes of the maxillary bones, and encroaches a little upon the palatines; this aperture is partly,* perhaps in young skulls wholly, bisected by a narrow longitudinal osseous bridge. In Mauge's Dasyure there are two large ovate apertures crossing the palato-maxillary sutures separated from each other by a broad plate of bone; posterior to these are two apertures of similar size and form, which, being situated nearer the mesial line, are divided by a narrower osseous bridge; each posterior external angle of the bony palate is also perforated by an oval aperture. In the Viverrine Dasyure the two vacancies which cross the palato-maxillary suture are in the form of longitudinal fissures, corresponding to the fourth and fifth grinders; the posterior margin of the bony palate has four small apertures on the same transverse line.

Now there is no carnivorous quadruped in the placental series which has a bony palate characterized by perforations and vacuities of this kind. In the Dog, the Cat, and the Weasel-tribe the bony palate is only perforated by two small oblique canals which open in or near the palato-maxillary suture. The very great interest which is attached to the fossil remains of the Stonesfield Marsupials, the only mammi-

* The large aperture in the skull of the *Dasyurus ursinus* figured by Temminck is the result of accidental injury to the bony palate. Monographies de Mammalogie, pl. viii.

ferous remains hitherto discovered in the secondary formations, will justify the minuteness, perhaps tediousness, with which I have dwelt on characters that, inclusive of the teeth, serve to distinguish the cranium of the Marsupial from that of any Placental quadruped. The structure of the bony palate in the Marsupials is interesting in other respects. Since the defective condition of this part of the cranium is one of the characteristics of the skull of the Bird, it might be expected that some approximation would be made to that structure in the animals which form the transition between the Placental and Oviparous Classes. We have already noticed the large vacuities which occur in the bony palate of nearly all the Marsupials; but this imperfectly ossified condition is most remarkable in the great *Perameles lagotis* and *Acrobates*. In the former (*fig*. 96) the bony

Fig. 96.

Perameles lagotis.

roof of the mouth is perforated by a wide oval space extending from the second premolars to the penultimate molars, exposing to view the vomer and the convolutions of the inferior spongy bones in the nasal cavity. Behind this space there are six small perforations, two in a transverse line midway between the great vacancy and the posterior margin of the bony palate, and four in a transverse line close to that margin. In *Acrobates* a still larger proportion of the posterior part of the palate is formed by membrane.

Cavity of the cranium.—The parietes of the cranial cavity are remarkable for their thickness in some of the Marsupial genera. In the Wombat the two tables of the parietal bones are separated posteriorly for the extent of more than half an inch, the insterspace being filled with a coarse cellular diploë; the frontal bones are about two and a half lines thick. In the Ursine Dasyure the cranial bones have a similar texture and relative thickness. In the Koala the texture of the cranial bones is denser, and their thickness varies from two lines to half a line. In the Kangaroo the thickness varies considerably in different parts of the skull, but the parietes are generally so thin as to be diaphanous, which is the case with the smaller Marsupials, as the Potoroos and Petaurists. The union of the body of the second with that of the third cranial vertebra takes place in the marsupial as in the placental Mammalia at the sella turcica, which is overarched by the backward extension of the lesser alæ of the sphenoid. The optic foramina and the fissuræ laceræ anteriores are all blended together, so that a wide opening leads outwards from each side of the sella. Immediately posterior and external to this opening are the foramina rotunda, from each of which in the Kangaroo a remarkable groove leads to the fossa Gasseriana at the commencement of the foramen ovale; the same groove is indicated in a slight degree in the Dasyures and Phalangers, but is almost obsolete in the Wombat and Koala. The carotid canals pierce the body of the sphenoid, as in Birds, and terminate in the skull very close together behind the sella turcica, which is not bounded by a posterior clinoid process. The sphenoidal bulla, which forms the chief part of the tympanic cavity in the *Perameles lagotis*, forms a large convex protuberance on each side of the floor of the cranial cavity in that species. The petrous bone in the Kangaroo, Koala, and Phalangers is impressed above the meatus auditorius by a deep, smooth, round pit, which lodges the lateral appendage of the cerebellum. The corresponding pit is shallower in the Dasyuri, and is almost obsolete in the Wombat. The middle and posterior fissuræ laceræ have the usual relative position, but the latter are small. The condyles are each perforated anteriorly by two foramina in most of the Marsupials, the Thylacinus forming the exception. Of the composition and form of the foramen magnum we have already spoken: it is of great size in relation to the capacity of the cranium; the aspect of its plane is backward and slightly downwards.

In the Kangaroo and Phalanger a thin ridge of bone extends for the distance of one or two lines into the periphery of the tentorial process of the dura mater, and two sharp spines are sent down into it from the upper part of the cranium in the *Phalangista vulpina*. The tentorium is supported by a thick ridge of bone in the Thylacine; but it is not completely ossified in any of the Marsupials: in some species, indeed, as the Dasyures, the Koala, and the Wombat, the bony crista above described does not exist. There is no ossification of the falciform ligament as in the Ornithorhynchus.

The anterior depression or olfactory division of the cavity of the cranium, as it may be termed from its large size, is separated in a well-marked manner from the proper cerebral division of the cavity. It is relatively smallest in the Koala. In all Marsupials it is bounded anteriorly by the cribriform plate of the æthmoid bone, which is converted into an osseous reticulation by the number and size of the olfactory apertures. The cavity of the nose, from its great size and the complication of the turbinated bones, forms an important part of the skull. It is divided by a complete bony septum to within one-fourth of the anterior aperture; the anterior margin of the septum is slightly concave in the Koala; describes a slight convex line in the Wombat, Kangaroo, and Phalanger, and a sigmoid flexure in the Dasyure. A longitudinal ridge projects downwards from the inside of each of the nasal bones, and is continued posteriorly into the superior turbinated bone; this bone extends into the dilated space anterior to the cranial cavity, which corresponds with the frontal sinuses. The convolutions of the middle spongy bone are extended chiefly in the axis of the skull; the processes of the anterior convoluted bone are arranged obliquely from below upwards and forwards. They are extremely delicate and numerous in the Dasyures and Phalangers; they consist of thin laminæ of bone beautifully arranged on the convex surface of the os turbinatum, and placed vertically to that surface in the Potoroo; but the bone becomes very simple in the Kangaroo, Koala, and Wombat. The nasal cavity communicates freely with large maxillary sinuses, and finally terminates by wide apertures behind the bony palate. In the skull the nasal cavity communicates with the mouth, as before mentioned, by means of the various large vacuities in the palatal processes.

Maxilla inferior.—The lower jaw of the Marsupials is a part of their osseous structure which claims more than ordinary attention in consequence of the discussions to which the fossil specimens of this bone discovered in the oolitic strata of Stonesfield have given rise. These specimens, which are well known to the English reader by the figures of them published in the Bridgewater Treatise of Dr. Buckland, and in the Elements of Geology of Mr. Lyell, were regarded by Cuvier as appertaining to the Marsupial series of Mammalia, and to be nearly allied to the genus *Didelphis.*

This opinion of the great founder of Oryctological Science has been called in question by other naturalists, and has been more especially opposed by Professor De Blainville, who conceives it to be more probable that they belong to a genus of Saurian Reptiles than to the *Didelphis* or any genus of insectivorous Mammals. I have examined the two specimens in the possession of Dr. Buckland, the specimen formerly in the collection of Mr. Broderip and now in the British Museum, and that which is preserved in the Museum at York. The composition of the lower jaw, each ramus of which consists of one piece of bone, the convex condyle, broad and high coronoid process, and the structure and mode of implantation of the molar teeth, sufficiently attest the mammiferous character of these remains: the size, elevation, and form of the coronoid process of the lower jaw, the process continued from the angle of the ramus, with the tubercular crowns of the molar teeth, indicate the carnivorous and insectivorous character of the species in question. In the presence of canines and the number of the incisors and molars, one of these small Insectivora (*Phascolotherium*) approaches most nearly to the smaller species of the modern genus *Didelphis;* while in the structure of the molar teeth, and in the form of the coronoid process, it very closely resembles the *Thylacinus.* The number of the molars in the other genus (*Thylacotherium*) exceeds that of any known ferine Insectivore, placental or marsupial. We have seen, however, that the marsupial *Myrmecobius* possesses nine molars on each side of both upper and lower jaws. Besides the osteological characters above alluded to, there is a peculiarity in the lower jaw of the Marsupial animals, which was first indicated by Cuvier in the genus *Didelphys,* but which is not restricted to that genus. In the carnivorous Marsupials, as the Thylacine, the lower maxillary bone resembles in general form that of the corresponding species in the placental series, as the Dog: a similar transverse condyle is placed low down near the angle of the jaw, on a level with the series of molar teeth; a broad and strong coronoid process rises high above the condyle, and is slightly curved backwards; there is the same well-marked depression on the exterior of the ascending ramus for the firm implantation of the temporal muscle, and the lower boundary of this depression is formed by a strong ridge extended downwards and forwards from the outside of the condyle. But in the Dog and other placental *Carnivora* (the seals excepted), a process, representing the angle of the jaw, extends directly backwards from the middle of the above ridge, which process gives precision and force to the articulation of the jaw, and increases the power by which the masseter acts upon the jaw. Now, although the same curved ridge of bone bounds the lower part of the external muscular depression of the ascending ramus in all the Marsupials, it does not in any of them send backwards, or in any other direction, a process corresponding to that just described in the Dog and other placental Carnivora. The angle of the jaw itself, in the Marsupials, is as if it were bent inwards in the form of a process encroaching in various shapes, and various degrees of development in the different Marsupial genera upon the interspace of the rami of the lower jaw. In looking directly upon the lower margin of the jaw, we see, therefore, in place of the margin of a vertical plate of bone, a more or less flattened triangular surface extended between the external ridge, and the internal process or inflected angle. This characteristic structure is clearly exemplified in the fossil jaw from the Stonesfield oolite, in the British Museum, representing the extinct Marsupial which I have termed *Phascolotherium Bucklandii*. In the *Opossums* the internal angular process is triangular and triedral, directed inwards, with the point slightly curved upwards, and more produced in the small than in the large species. In the Dasyures it has a similar form, but the apex is extended into an obtuse process. In the Thylacine the base of the inverted angle is proportionally more extended, and a similar structure is presented by the fossil Phascolothere. In the Perameles the angle of the jaw forms a still longer process; it is of a flattened form extended obliquely inwards and backwards and slightly curved upwards. It presents a triangular, slightly incurved, and pointed form in the *Petaurists*, in which it is longest and weakest in the pigmy species, (*Acrobates*, Desm.) It is shorter and stronger in the *Myrmecobius* (*fig.* 97). In the Potoroos and Phalangers the process is broad with the apex slightly developed; it is bent inwards and bounds the lower part of a wide and deep depression in the inside of the ascending ramus. In the great Kangaroo the internal margin of this process is curved upwards, so as to augment the depth of the internal depression above mentioned. The internal angular process arrives at its maximum of development in the Wombat, (*fig.* 94,) and the breadth of the base of the ascending ramus very nearly equals the height of the same part. This broad base also inclines downwards and outwards from the inflected angle, and the same peculiarity occurs in the jaw of the Phascolothere. In the Koala the size of the process in question is also considerable, but it is compressed, and directed backwards with the obtuse apex only bending inwards, so that the characteristic flattening of the base of the ascending ramus is least marked in this species. There is no depression on the inner side of the ramus of the jaw in the Koala, but its smooth surface is simply pierced near its middle by the dental artery. The surface of the external muscular depression bounded below by a broad angular ridge, as above described, is entire in the Dasyures, Opossums, Bandicoots, Petaurists, and Phalangers; but in the Wombat the outer surface of the ascending ramus is directly perforated by a round aperture immediately posterior to the commencement of the dental canal:* the corresponding aperture is of larger size in the Kangaroo. But in the Potoroos both the external and internal depressions of the ascending ramus lead to wide canals, or continuations of the wide depressions which pass forwards into the substance of the horizontal ramus, and soon uniting into one passage, leave a vacant space in the intervening bony septum. This structure, if it had been observed only in the jaw of a fossil Marsupial, would have supported an argument for its Saurian nature, more cogent than any that have been adduced in the discussion of the Stonesfield fossils, on account of the analogous vacuity in the jaw of the Crocodile.

Fig. 97.

Lower jaw, Myrmecobius.

* A bristle is represented passing through this aperture in fig. 94.

The commencement of the dental canal in the Potoroos and Wombat is parallel with the beginning of the molar series, and it has the same relative position in the Stonesfield Marsupials; but in the other carnivorous and insectivorous species the dental foramen is placed further back. In the Wombat a vascular groove is continued from the foramen along the inner side of the ramus of the jaw as in the Stonesfield fossils; and a corresponding but wider groove is present in the lower jaw of the Myrmecobius. In the Thylacine and Ursine Dasyures and their fossil congener the Phascolothere, the condyle of the lower jaw is placed low down, on a level with the molar series: it is raised a little above that level in the smaller Dasyures and Opossums, and ascends in proportion to the vegetable diet of the species.

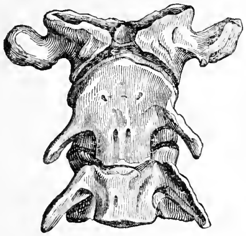
In all those Marsupials which have few or very small incisors the horizontal rami of the jaw converge towards a point at the symphysis. The angle of convergence is most open in the Wombat, and the gradual diminution in the size of the rami as they approach this part is most marked and direct. The internal surface of the *symphysis menti* is almost horizontal, and is convex from side to side in the interval between the molars and incisors. The suture becomes obliterated in aged individuals. It is also wholly obliterated in the skull of a Koala now before me; in all the other Marsupial crania which I have examined, the rami of the lower jaw are disjoined at the symphysis; and in the Opossum, both the rami of the lower jaw and all the bones of the face are remarkable for the loose nature of their connection.

Vertebral column.—The vertebral column is divisible in all the Marsupials into the usual classes of cervical, costal, lumbar, sacral, and caudal vertebræ. The cervical vertebræ invariably present the usual number, seven, and the usual character of the perforation of the transverse process, or rather the presence of the upper and lower transverse processes, and the union of their outer extremities with a rudimental rib. I found the cervical ribs of the dentata distinct and unanchylosed in a mature Perameles. In the Dasyures, Opossums, Bandicoots, and Phalangers, the seventh cervical vertebra has only the upper transverse process, and consequently wants the character of the perforation, as in many of the ordinary Mammalia. In the Petaurists, Koala, Wombat, Potoroos, and Kangaroos, the seventh vertebra is perforated like the rest. But in the Kangaroo both the dentata and atlas have the transverse processes grooved merely by the vertebral arteries; and in the Koala and Wombat the atlas presents only the perforation on each side of the superior arch. In the Perameles and some other Marsupials, as the Cayopollin, an affinity to the cold-blooded Ovipara is manifested in the structure of the atlas (*fig*. 98), which exhibits a permanent separation of the neurapophyses or superior laminæ from the centre or body below. In the Koala and Wombat the body of the atlas remains permanently cartilaginous, and the lower part of the vertebral ring is completed by dried gristly substance (*fig*. 99). In the Petaurists, Kangaroos,

Fig. 98.

Atlas of Perameles lagotis.

Fig. 99.



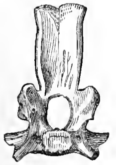
Atlas, axis, and third cervical vertebra, Koala.

and Potoroos, the atlas is completed below by an extension of ossification from the neurapophyses into the cartilaginous nucleus representing the body, and the ring of the vertebra is for a long time interrupted by a longitudinal fissure in the middle line, the breadth of which diminishes with age. This fissure is represented in figures of the atlas of a Potoroo and Kangaroo, given by Pander and D'Alton, (*Beutelthiere*, *fig*. c, *plates* iii. & vii.); but in some of the skeletons of these Marsupials examined by me I find the ring completed and the fissure obliterated. In all the Marsupials the spine of the dentata is well developed both in the vertical and longitudinal directions, but most so in the Virginian and Crab-eating Opossums, (*fig*. 100), where it increases in thickness posteriorly; in these species also the third, fourth, and fifth cervical vertebræ have their spines remarkably long and thick, but progressively diminishing from the third (*fig*. 101), which equals in height and

Fig. 100.

Vertebra dentata, Didelphys Virginiana.

Fig. 101.



Third cervical vertebra, Didelphys Virginiana.

thickness, but not in longitudinal extent, the spine of the dentata. These spines are four-sided, and being closely impacted together, one behind another, must add greatly to the strength, while they diminish the mobility of this part of the spine. I know of no other mammiferous genus which presents the same structure: in the Armadillos the corresponding spines are largely developed, but they are anchylosed together. In the Orang the cervical spines are very long and strong, but have the ordinary sub-cylindrical rounded form. Tyson, who has described and figured the above structure of the cervical vertebræ in his anatomy of the Opossum, conjectures that it is given to this arboreal animal in order "that there might be no danger of its breaking its neck should it happen to fall to the ground by chance or design:" but this teleological conjecture is invalidated by the fact that the Phalangers, Petaurists, Koala, and other arboreal Marsupials present the usual structure of the five posterior cervical vertebræ, the spines of which are much smaller and weaker than that of the dentata, and in the Phalangers and Petaurists almost obsolete. These do not require the neck to be strengthened to aid in overcoming the struggles of a resisting prey. I observe in the *Phalangista Cookii* that the superior flattened arches of the five last cervical vertebræ bear a ridge on each side of the spine having the same direction and form, and nearly the same size. The structure of the transverse processes of the cervical vertebræ, in the Opossum, is adapted to the strengthening and fixation of this part of the vertebral column: they are expanded nearly in the axis of the spine, but obliquely, so that the posterior part of one transverse process overlaps the anterior part of the succeeding. This structure is exhibited in a slighter degree in the cervical vertebræ of the Dasyures, Phalangers, and Great Kangaroo. In the Petaurists, Potoroos, Wombat, and Koala, the direction and simpler form of the transverse processes allows of greater freedom of lateral motion. In the Koala and Wombat a short obtuse process is given off from the under part of the transverse process of the sixth cervical vertebra. In the Potoroos, Kangaroos, Petaurists, Phalangers, Opossums, and Dasyures, this process is remarkably expanded in the direction of the axis of the spine. In the Bandicoots corresponding processes are observed progressively increasing in size, on the fourth, fifth, and sixth cervical vertebræ.

The number of the dorsal vertebræ is greatest in the Wombat, where it is fifteen, corresponding with the number of pairs of ribs: it is least in the Petaurists, which have twelve dorsal vertebræ.* In all the other genera there

* In the skeletons both of the *Pet. macrurus* and *Pet. sciureus* in the Museum of the College of Surgeons there are twelve pairs of ribs; but in the *Pet. macrurus* the succeeding vertebra has a short transverse process on each side, the extremity of which has the appearance of having supported a costal appendage. Cuvier, however, assigns but twelve dorsal vertebræ to this species in his table. Leç. d'Anat. Comp. 2d edit. p. 180.

are thirteen dorsal vertebræ and thirteen pairs of ribs.*

In the Koala the length of the spine of the first dorsal hardly exceeds that of the last cervical, but in all other Marsupials the difference is considerable, the first dorsal spine being much longer: those of the remaining dorsal vertebræ progressively diminish in length and increase in breadth and thickness. They slope backwards towards the centre of motion, which in Mauge's Dasyure is shown to be at the ninth dorsal vertebra, by the verticality of its spine, towards which both the preceding and succeeding spines incline. In the *Perameles* the centre of motion is at the eleventh dorsal vertebra, in the Potoroo and Kangaroo at the twelfth, in the Petaurists at the thirteenth vertebra. In the Phalangers, Opossum, Koala, and Wombat the flexibility of the spine is much diminished, and the centre of motion is not defined by the convergence of the spinous process towards a single vertebra, but they all incline slightly backwards.

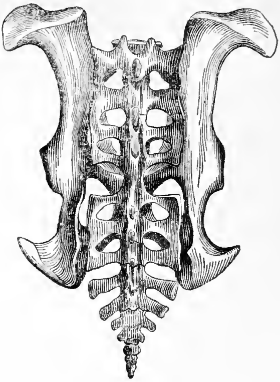
The lumbar vertebræ are four in number in the Wombat, seven in the *Petaurists*, and six in other Marsupialia; the total number of true vertebræ being thus the same in all the genera.†

The pressure which the trunk of the Wombat must occasionally have to resist in its extensive subterranean burrows, is probably the condition of the development of the additional pairs of ribs in that species.

The anterior oblique processes, which begin to increase in length in the three posterior dorsal vertebræ, attain a great size in the lumbar vertebræ, and are locked into the interspace of the posterior oblique processes which are double on each side, except in the Perameles, and in the last lumbar vertebræ of all the other genera. The transverse processes of the lumbar vertebræ progressively increase in length as the vertebræ approach the sacrum; they are most developed in the Wombat, where they are directed obliquely forwards. In the Kangaroos, Potoroos, and Perameles, they are curved forwards and obliquely downwards. The length of these and of the anterior oblique processes is relatively least in the Petaurists, Phalangers, and Opossums.

Sacrum.—The number of vertebræ succeeding the lumbar which are anchylosed together in the sacral region of the spine, amounts in the Wombat to seven (*fig.* 102), but if we regard those vertebræ only as sacral which join the ossa innominata, then there are but three. In the Phalangers there are generally two sacral vertebræ, but in the *Phalangista Cookii* the last lumbar assumes the character of the sacral vertebræ both by anchylosis and partial junction with the ossa innominata.

Fig. 102.



Pelvis of the Wombat.

In the Kangaroos and Potoroos the impetus of the powerful hinder extremities is transferred to two anchylosed vertebræ. In the Perameles there is only a single sacral vertebra, the spine of which is shorter and thicker than those of the lumbar vertebræ, and is turned in the contrary direction, viz. backwards.

In the Myrmecobius there are four sacral vertebræ by anchylosis, two of which join the ilia. In Mauge's Dasyure, two sacral vertebræ are anchylosed, but it is to the expanded transverse processes of the anterior one only that the ossa innominata are joined. The same kind of union exists in the Viverrine Dasyure, but three vertebræ are anchylosed together in this species. In the Phalangers and Petaurists there are two sacral vertebræ. In *Petaurus macrurus* three are anchylosed together, though only two join the ilium. In the Wombat (*fig.* 102) the transverse processes of the numerous anchylosed vertebræ are remarkable for their length and flatness, those of the first four are directed outwards and are confluent at their extremities; the remaining ones are turned in a slight degree backwards, and very nearly reach the tuberosities of the ischia, behind which they gradually diminish in size and disappear in the three last caudal vertebræ. The transition from the sacral to the caudal vertebræ is very obscure in the Wombat. If we limit the sacral to the three which join the ilium, then there remain twelve vertebræ for the tail. The spinal canal is complete in all but the last three, which consist only of the body. There are no inferior spines, and as only the six posterior vertebræ, which progressively diminish in length, extend beyond the posterior aperture of the pelvis, the tail is scarcely visible in the living animal. In the Koala (*fig.* 109) the tail is also very short. In the Chæropus it seems to be wanting. In one species of Perameles I find eighteen caudal vertebræ; in

* Cuvier assigns only twelve dorsal vertebræ to the Kangaroo Rat, but in two different species of *Hypsiprymnus* in the Mus. Coll. Surgeons, there are thirteen dorsal and six lumbar vertebræ, and I observed the same number in the skeletons of *Hypsiprymnus ursinus* and *dorcocephalus* in the Leyden Museum. Pander and D'Alton figure thirteen dorsal vertebræ in the *Hypsiprymnus murinus*.

† In *Phal. Cookii* the sixth lumbar vertebra is joined by a part of its transverse processes to the ossa innominata.

another twenty-three. In two species of Potoroo there are twenty-four caudal vertebræ, but the relative length of the tail differs in these by one-third, in consequence of the different length of the bodies of the vertebræ. In *Hypsiprymnus ursinus* there are more than twenty-six caudal vertebræ. In the great Kangaroo there are twenty-two caudal vertebræ. In Bennett's Kangaroo there are twenty-four caudal vertebræ, which are remarkable for their size and strength. In the *Phalangista vulpina*, there are twenty-one caudal vertebræ. In the *Petaurus macrurus* I find twenty-eight caudal vertebræ, while in the *Pet. sciureus* there are but twenty; the bodies of the middle caudal vertebræ in both these species are remarkably long and slender. The Myrmecobius has twenty-three caudal vertebræ. In the *Dasyurus Maugei* I find twenty caudal vertebræ; in *Didelphis cancrivora* there are thirty-one; in the Virginian Opossum there are twenty-two caudal vertebræ. In the latter species the spinal canal is continued along the first six; beyond these the superior spinous processes cease to be developed, and the body gives off, above, only the two anterior and two posterior oblique processes, which are rudimental, and no longer subservient to the mutual articulation of the vertebræ. The transverse processes are single on the first five caudal vertebræ, and are nearly the breadth of the body, but diminish in length from the second caudal, in which vertebræ they are generally the longest. In the other vertebræ a short obtuse process is developed at both extremities of the body on either side, so that the dilated articular surfaces of the posterior caudal vertebræ present a quadrate figure.

In most of the Marsupials which have a long tail, this appendage is subject to pressure on some part of the under surface. In the Kangaroo (*fig.* 103,) this must obviously take place to a considerable degree when the tail is used as a fifth extremity, to aid in supporting or propelling the body. In the Potoroos and Bandicoots the tail also transmits to the ground part of the superincumbent pressure of the body by its under surface, when the animal is erect, but it is not used as a crutch in locomotion as in the Kangaroos. In the Phalangers and Opossums the tail is prehensile, and the vessels situated at the under surface are liable to compression when the animal hangs suspended by the tail. To protect these vessels, therefore, as well as to afford additional attachment to the muscles which execute the various movements for which the tail is adapted in the above mentioned Marsupials, V-shaped bones, or inferior arches (hæmapophyses) are developed, of various forms and sizes, and are placed opposite the articulations of the vertebræ, a situation which is analogous to that of the superior arches in the sacral region of the spine in Birds, and in the dorsal region of the spine in the Chelonian Reptiles. The two crura of the sub-vertebral arch embrace and defend the bloodvessels, and the spinous process continued from their point of union presents a variety of forms in different genera.

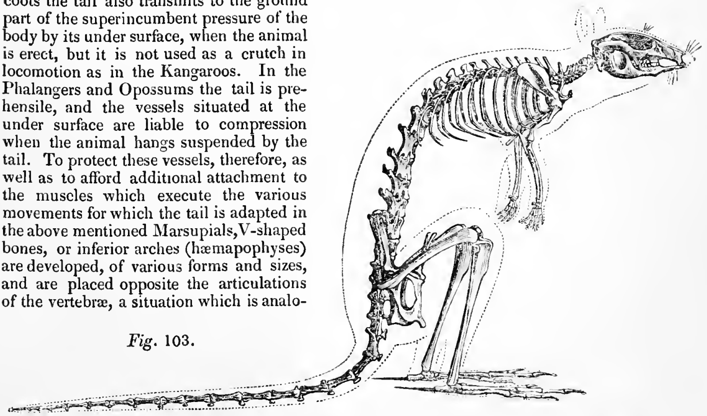
Fig. 104.

Terminal caudal vertebræ.

In Cook's Phalanger I find the hæmapophyses commence between the second and third caudal vertebræ, increase in length to the fourth, and then progressively diminish to the end of the tail; the penultimate and anteepnultimate presenting a permanent separation of the lateral moieties, and an absence of the spine (*fig.* 104.)

In the Virginian Opossum and Vulpine Phalanger they are simple, about a quarter of an inch in length where longest, and directed obliquely forwards, and diminish in size as they approach the extremity of the tail. In the Potoroos the extremity of the long anterior spines is dilated and produced both backwards and forwards; the posterior smaller ones become expanded laterally, and give off similar but shorter processes from each side, whereby the base of support is extended. In the Great Kangaroo the spine of the first subvertebral arch only is simple and elongated, the extremities of the others are expanded, and in some jut out into four obtuse processes, two at the sides, and two at the anterior and posterior surfaces. In a carefully prepared skeleton of *Macropus Bennettii* in the Museum of the Zoological Society, I found these inferior spines want-

Fig. 103.



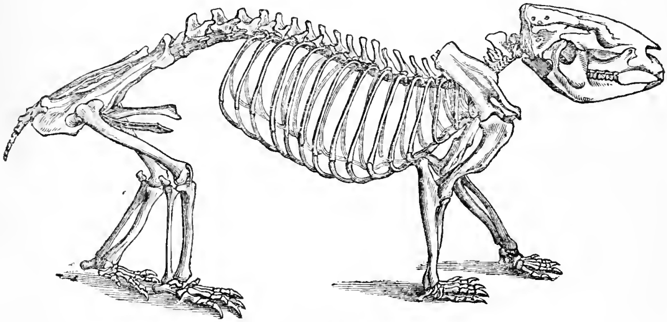
Macropus elegans.

ing between the last nine vertebræ of the tail. In the Petaurists, Phascogales, and Dasyures, where the tail acts as a balancing pole, or serves, from the long and thick hair with which it is clothed, as a portable blanket to keep the nose and extremities warm during sleep, the subvertebral arches are also present, but in less number and of smaller relative size. They are here principally subservient to the attachment of muscles, their more mechanical office of defending the caudal vessels from pressure not being required.

Thorax.—The ribs consist of thirteen pairs, except in the Wombat, which has fifteen, and Petaurists, which have twelve; the first is the shortest, and, except in some of the Petaurists, the broadest. In the *Pet. macrurus* the fifth, sixth, or seventh are the broadest, and the ribs generally have, both in this species and in *Pet. sciureus*, a more compressed form than in the other Marsupials; but this character does not exist in *Petaurus Taguanoides*. In the Great Kangaroo they are very slender and rounded, except at the sternal extremities, which are flattened for the attachment of the cartilages. In this species and the Bush Kangaroo, the seven anterior pairs of ribs articulate directly with the sternum. The cartilages of the six false pairs are long and bent towards the sternum, but do not join it, nor are they confluent, but have a gliding motion one over the other.

In the Myrmecobius there are eight pairs of true ribs; the two last pairs are floating ribs. In the Opossum there are seven pairs of true ribs, and six which may be regarded as *costæ nothæ*. In the Petaurist six pairs out of the twelve, and in the Wombat six pairs only out of the fifteen, reach the sternum (*fig.* 105).

Fig. 105.



Phascolomys fusca.

The *sternum* consists of a succession of elongated bones, generally six in number, but in the *Petaurus Taguanoides* five, and in the Wombat four.

The first bone, or manubrium sterni, is the largest, and presents in many species a triangular shape from the expansion of its anterior part, and sometimes a rhomboidal figure. A strong keel or longitudinal process is given off in many species from the middle of its inferior or outer surface; the side next the cavity of the chest is smooth and slightly concave. In the Wombat, Phalangers, and others, the keel is produced anteriorly into a strong process, against the sides of which the clavicles abut: the first pair of ribs join the produced anterior angles of the manubrium.

In the Dasyures, Opossums, Phalangers, and Petaurists, the manubrium is compressed and elongated, and the clavicles are joined to a process continued from its anterior extremity; the small clavicles of the Kangaroo have a similar connexion.

The cartilages of the true ribs (which frequently become ossified in old Marsupials) are articulated as usual to the interspaces of the sternal bones; the last of these supports a broad flat cartilage.

Of the Pectoral Extremities.—The *scapula* varies in form in the different Marsupials. In the Petaurists it forms a scalene triangle, with the glenoid cavity at the convergence of the two longest sides.

In the Wombat it presents a remarkably regular oblong quadrate figure, the neck being produced from the lower half of the anterior margin, and the outer surface being traversed diagonally by the spine, which in this species gradually rises to a full inch above the plane of the scapula, and terminates in a long narrow compressed acromion arching over the neck to reach the clavicle.

In the Koala (*fig.* 106), the superior costa does not run parallel with the inferior, but recedes from it as it advances forwards, and then passes down, forming an obtuse angle, and with a gentle concave curvature to the neck of the scapula; a small process extends from the middle of this curvature. In the Potoroo, the upper costa is at first parallel with the lower, but this parallel part is much shorter; the remainder describes a sigmoid flexure as it approaches the neck of the scapula.

In the Great Kangaroo, the Perameles, Phalangers, Opossums, and Dasyures, the whole upper costa of the scapula describes a sigmoid

Fig. 106.

Scapula of Koala.

curve, the convex posterior position of which varies as to its degree and extent.

The subscapular surface is remarkable in the Perameles for its flatness, but presents a shallow groove near the inferior costa. In most other Marsupials it is more or less convex or undulating.

In the Great Kangaroo the supra-spinal fossa is of less extent than the space below the spine, and the spine is inclined upwards. In the Perameles and Dasyures the proportions of the supra and infraspinal surfaces are reserved, and the whole spine is bent downwards over the infraspinal surface. In the Potoroos and Phalangers the acromion is, as it were, bent downwards so as to present a flattened surface to the observer. In the Potoroos and Opossums this appearance is produced by a true expansion of the acromion. In the Perameles the coracoid process is merely represented by a slight production of the superior part of the glenoid cavity. In the Kangaroo and Potoroo it forms a protuberance on the upper part of the head of the scapula. In the other Marsupials it assumes the character of a distinct process from the same part, and attains its greatest development in the Wombat and Koala, in the latter of which it is forcibly curved downwards and inwards.

The *clavicles* are present in all the Marsupials, with the exception of the genus *Perameles*, and probably also the *Chæropus*. In the claviculate Marsupials they are relatively strongest and longest in the burrowing Wombat, weakest and shortest in the Great Kangaroo. In the latter they are simply curved with the convexity forwards, and measure only two inches in length. In the Wombat they are upwards of three inches in length, and have a double curvature; they are expanded and obliquely truncate at the sternal extremity, where the articular surface presents a remarkably deep notch: they become compressed as they approach the acromion, to which they are attached by an extended narrow articular surface.

In the Koala the clavicles are also very strong, but more compressed than in the Wombat, bent outwards in their whole extent, and the convex margin formed, not by a continuous curve, but by three almost straight lines, with intervening angles; progressively diminishing in extent to the outermost line which forms the articular surface with the acromion. In the Myrmecobius the clavicles are subcompressed and more curved at the acromial than at the sternal end. In most of the other Marsupials the clavicle is a simple compressed elongated bone, with one general outward curvature.

The *humerus* in the Dasyures and Thylacines resembles that of the Dog-tribe in the imperforate condition of the inner condyle, but differs in the more marked development of the muscular ridges, especially of that which extends upwards from the outer condyle for the origin of the great supinator muscle. This ridge is terminated abruptly by the smooth tract for the passage of the musculo-spiral nerve.

In all the other genera of Marsupials that I have examined the internal condyle of the humerus is perforated. But in some species of *Petaurus*, as *Petaurus sciureus*, the foramen is represented by a deep notch; and in the *Phalangista Cookii*, both foramen and notch are wanting.* The ridge above the external condyle is much developed in the *Petaurus macrurus* and *sciureus*, and notched at its upper part, but this notch does not exist in *Pet. taguanoides*. I find similar differences in the development of the supinator, or outer ridge, in the genus *Perameles;* in the *Per. lagotis* it is bounded above by a groove; in *Per. Gunnii* it is less developed and less defined. In the Kangaroos, Potoroos, Wombat, and Koala (*fig.* 107), the outer condyloid ridge extends in the form of a hooked process above the groove of the radial nerve. In all these, and especially in the Wombat, the deltoid process of the humerus is strongly developed; it is continued from the external tuberosity down the upper half of the humerus; except in the Petaurists, where, from the greater relative length of the humerus, it is limited to the upper third.

The interspace of the condyles is occasionally perforated, as in the *Perameles lagotis* and Wombat. The articular surfaces at both extremities of the humerus have the usual form; but it may be observed in some Marsupials, as the Koala, that at the distal articulation the external convexity for the radius has a greater relative extent than usual, and the ulnar concavity is less deep.

Fig. 107.

Humerus of the Koala.

The bones of the fore-arm present little to detain our notice. They are always distinct and well developed, and their adaption to pronation and supination is complete. The prehensile faculty and unguiculate structure of the anterior extremities appear to have been indispensable to animals where various manipulations were required in the economy of the marsupial pouch. When, therefore, such an animal is destined like the ruminant to range the wilderness in quest of pasturage, the requisite powers of the anterior members are retained and secured to it, as has been already observed, by an enormous developement of the hinder extremities, to which the function of locomotion is restricted.

* In the other species of *Phalangista*, and in the *Petaurus taguanoides* and *macrurus*, the internal condyle of the humerus is perforated.

We find, therefore, that the bones of the fore-arm of the Kangaroo differ little from those of the burrowing Wombat, the climbing Koala, or the carnivorous Dasyure, save in relative size. They present the greatest proportional strength in the Wombat, and the greatest proportional length and slenderness in the Petaurists or Flying Opossums, in which the radius and ulna are in close contact through a great portion of their extent, and thus lend a firmer support to the outstretched dermal parachute. They are also long and slender in the Koala. In general the radius and ulna run nearly parallel, and the interosseous space is very trifling. It is widest in the Potoroos. The olecranon is well developed in all the Marsupials. In the Virginian Opossum and Petaurists we find it more bent forwards upon the rest of the ulna, than in the other Marsupials. In the Wombat, where the acromion is the strongest, and rises an inch and a half above the articular cavity of the ulna, it is extended in the axis of the bone. The distal end of the radius in this animal is articulated to a bone representing the os scaphoides and os lunare.

The ulna, which in the same animal converges towards a point at its distal end, has that point received in a depression formed by the cuneiform and pisiform bones; these are bound together by strong ligaments, and the pisiform then extends downwards and backwards for two-thirds of an inch. The second row of the carpus consists of five bones. The trapezium supports the inner digit, and has a small sesamoid bone articulated to its radial surface. The trapezoides is articulated to the index digit, and is wedged between the scapho-lunar bone and os magnum; this forms an oblique articular surface for the middle digit; but the largest of the second series of carpal bones is cuneiform, which sends downwards an obtuse rounded process, and receives the articular surface of the fifth, and the outer half of that of the fourth digit, the remainder of which abuts against the oblique proximal extremity of the middle metatarsal bone.

The five metacarpal bones are all thick and short, but chiefly so the outermost. The innermost digit, or pollex, has two phalanges, the remainder three; the ungueal phalanx of all the digits is conical, curved, convex above, expanded at the base, and simple at the opposite extremity.

In the Perameles the ungueal phalanx of the three middle digits of the hand, and of the two outer digits of the foot, are split at the extremity by a longitudinal fissure commencing at the upper part of the base. This structure, which characterizes the ungueal phalanges in the Placental Anteaters, has not been hitherto met with in other Marsupial genera.*

The terminal phalanges of the Koala are large, much compressed and curved; the concave articular surface is not situated, as in the cats, on the lower part of the proximal end, but, as in the sloths, at the upper. The claws which they support are long.

* It would be interesting to examine the skeleton of the *Chæropus*, with reference to this structure.

In the Great Kangaroo the first row of the carpus is composed, as in the Wombat, of three bones, but the apex of the ulna rotates in a cavity formed exclusively by the cuneiforme. There are four bones in the second row; of which the unciform is by far the largest, and supports a part of the middle, as well as the two outer digits. In the Potoroos I find but three bones in the distal series of the carpus, the trapezoides being wanting, and its place in one species being occupied by the proximal end of the second metacarpal bone, which articulates with the os magnum. In the Perameles there are four bones in the second carpal row, although the hand is less perfect in this than in any other Marsupial genus, *Chæropus* excepted, the three middle toes only being fully developed.

In the Petaurists the carpus is chiefly remarkable for the length of the *os pisiforme*.

It would be tedious to dwell on the minor differences observable in the bony structure of the hand in other Marsupials. I shall therefore only observe that though the inner digit is not situated like a thumb, yet that the fingers enjoy much lateral motion, and that those at the outer can be opposed to those at the inner side so as to grasp an object and perform, in a secondary degree, the function of a hand. In the Koala the two inner digits are more decidedly opposed to the three outer ones than in any other climbing Marsupial. But some of the Phalangers, as the *Ph. Cookii* and *Ph. gliriformis* of Bell, present in a slighter degree the same disposition of the fingers, by which two out of the five have the opposable properties of a thumb. I have observed a similar disposition of the digits in the act of climbing in the Dormouse, and it probably is not uncommon in other placental Mammalia of similar habits and which have long, slender, and freely moveable fingers. As a permanent disposition of the digits, the opposition of three to two is most conspicuous in the prehensile extremities of the Chameleon.

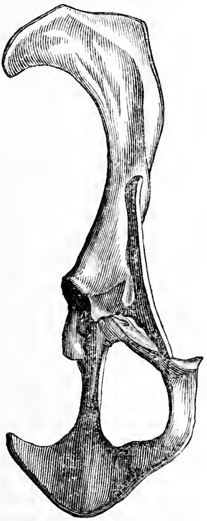
Of the Pelvic Extremities.—The pelvis (*fig.* 109) in the mature Marsupials is composed of the os sacrum, the two ossa innominata, and the characteristic supplemental bones, attached to the pubis, called by Tyson the *ossa marsupialia* or *Janitores Marsupii*.

We seek in vain for any relationship between the size of the pelvis and that of the new-born young, the minuteness of which is so characteristic of the present tribe of animals. The diameters both of the area and apertures of the pelvic canal are always considerable, but more especially so in those Marsupialia which have the hinder extremities disproportionately large; as also in the Wombat, where the pelvis is remarkable for its width. The pelvis is relatively smallest in the Petaurists; but even here the diameter of the outlet is at least six times that of the head of the new-born young.

The anterior bony arches formed by the ossa pubis and the ischia are always complete, and the interspace between these arches is divided, as in other Mammalia, into the two obturator foramina by an osseous bridge continued from the pubis to the ischium on each side of the symphysis.

In the Kangaroos, Potoroos, Phalangers, and Opossums the ilia offer an elongated prismatic form. They are straight in the Opossum, but gently curved outwards in the other Marsupial genera. In the Dasyures there is a longitudinal groove widening upwards in place of the angle at the middle of the exterior surface of the ilium. The ilia in the Petaurists are simply compressed, with an almost trenchant anterior margin. They are broader and flatter in the Perameles, and their plane is turned outwards. But the most remarkable form of the ilia is seen in the Wombat, in which they are considerably bent outwards at their anterior extremity. In the Kangaroos and Potoroos the eye is arrested by a strong process given off from near the middle of the ileo-pubic ridge, and this process may be observed less developed in the other Marsupialia. The tuberosity of the ischia inclines outwards in a very slight degree in the Dasyures, Opossums, Phalangers, Petaurists, and Perameles, in a greater degree in the Kangaroos and Potoroos, and gives off a distinct and strong obtuse process in the Wombat, (*fig.* 108,) which

Fig. 108.

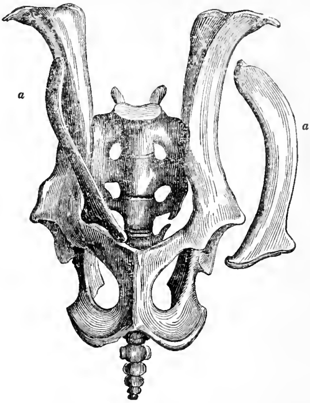


Right os innominatum and marsupial bone, Wombat.

not only extends outwards but is curved forwards. In the Potoroos the symphysis of the ischia, or the lower part of what is commonly called the symphysis pubis, is produced anteriorly. The length of this symphysis, and the straight line formed by the lower margin of the ischia is a characteristic structure of the pelvis in most of the Marsupials.

The Marsupial bones (*a, a, fig.* 109) are

Fig. 109.



Pelvis and marsupial bones of the Koala.

elongated, flattened, and more or less curved, expanded at the proximal extremity, which sometimes, as in the Wombat, is articulated to the pubis by two points; they are relatively straightest and most slender in the Perameles; shortest in the Myrmecobius, where they do not exceed half an inch in length; longest, flattest, broadest, and most curved in the Koala, where they nearly equal the iliac bones in size. They are always so long that the cremaster muscle winds round them in its passage to the testicle or mammary gland, and the uses of these bones will be described in treating of that muscle.

With reference to the interesting question—What is the homology or essential nature of the ossa marsupialia? I entirely concur in the opinion first advanced by the able anatomist, M. Laurent,* viz. that they belong to the category of the trochlear ossicles, commonly called sesamoid, and are developed in the tendon of the external oblique which forms the mesial pillar of the abdominal ring, as the patella is developed in the tendon of the *rectus femoris.* I had arrived at this conclusion from independent researches, and unaware of any prior announcement of this view when I discussed the question before the Zoological Society in 1835.† I cannot, however, participate in the opinion of M. Laurent and the celebrated De Blainville, that the marsupial bones are superadded to the abdominal muscles to aid in an unusually energetic compression required to expel the uterine fœtus. It is not in the females of those animals which give birth to the smallest

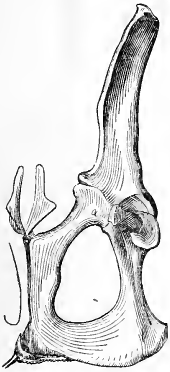
* See his note inserted in the 'Bulletin des Sciences Médicales' of Férussac, 1827, No. 77, p. 112, and the Annales d'Anat. et de Physiologie, 1839, p. 240.

† See the abstract of a paper on the anatomy of the *Dasyurus*, Proc. Zool. Soc., January, 1835.

fœtuses that we ought to find auxiliary parts for increasing the power of the muscles engaged in parturition. The bones in question are, moreover, equally developed in both sexes: and they are so situated and attached that they add to the power of the muscles which wind round them, and not of those implanted in them. They are not, however, merely subservient to add force to the action of the "cremasteres," but give origin to a great proportion of the so-called "pyramidales."

The *osteogenesis* of the marsupial pelvis derives some extrinsic interest from the not yet forgotten speculations which have been broached regarding the analogies of the marsupial bones. These have been conjectured to exist in many of the placental Mammalia, with a certain latitude of altered place and form, disguised, *e. g.* as the bone of the *penis* in the Carnivora, or appearing as the supplemental ossicles of the acetabulum, which exist in the young of many of the Rodentia. In the os innominatum of the immature Potoroo the curved prismatic *ilium* contributes to form, by the outer part of its base, the upper or anterior third of the acetabulum; the rest of the circumference of this cavity is completed by the *ischium* and *pubis*, excepting a small part of the under or mesial margin, which is formed by a distinct ossicle or epiphysis of the ilium, (*a*, *fig*. 110,) analogous to that described by Geoffroy St. Hilaire as the rudimental marsupial bone in the rabbit. Now here there is a co-existing marsupial bone: but besides the five separate bones just mentioned, there is a sixth distinct triangular ossicle, which is wedged into the posterior interspace of the ischio-pubic symphysis. How easy were it to suggest that this single symmetrical bone may be the representative of the *os penis* removed from the glans to the root of the intromittent organ! I regard it as a mere epiphysis of the ischium. The circumference of the acetabulum is always interrupted by a deep notch opposite the obturator foramen, which is traversed by a ligamentous bridge, and gives passage to the vessels of the Harderian gland lodged in the wide and deep acetabular fossa.

Fig. 110.



The penial like the marsupial bone is essentially an ossification of the fibrous or sclerous tissue.

The *femur* is a straight, or nearly straight, long, cylindrical bone, having a hemispherical head supported on a very short neck, especially in the Petaurists, and situated here almost in the axis of the shaft, above and between the two trochanters, which are nearly of equal size. In the Kangaroos and Potoroos the head of the thigh-bone is turned more inwards, and the outer or greater trochanter rises above it. In other Marsupials the great trochanter is less developed. In most of the species a strong ridge is continued downwards to within a short distance from the trochanter, and this ridge is so produced at the lower part in the Wombat as almost to merit the name of a third trochanter. In the Wombat and Koala there is no depression for a ligamentum teres. The shaft of the bone presents no *lineæ asperæ*.

The canal for the nutrient artery commences at the upper third and posterior part of the bone in the Koala, and extends downwards, contrariwise to that in most other marsupial and placental Mammalia.

At the distal extremity of the femur the external condyle is the largest, the internal rather the longest. The intermediate anterior groove for the patella is well marked in the *Perameles*, where the patella is fully developed, but is broad and very shallow in the Phalangers and Dasyures, where the tendon of the rectus muscle is merely thickened or offers only a few irregular specks of ossification; and the corresponding surface in the Petaurists, Wombat, and Koala is almost plane from side to side; in these Marsupials and in the Myrmecobius the patella is wanting. I find a distinct but small bony patella in the *Macropus Bennettii*. There is a sesamoid bone above and behind the external condyle of the femur in the Myrmecobius and some other Marsupials.

In the knee-joint, besides the two crucial ligaments continued from the posterior angles or cresses of the semilunar cartilages—one to the outer side of the inner condyle, the other to the interspace of the condyles—there is a strong ligament which passes from the anterior part of the tibial protuberance backwards to the inner side of the fibular condyle, and a second continued from the same point along the outer margin of the outer semilunar cartilage to the head of the tibia.

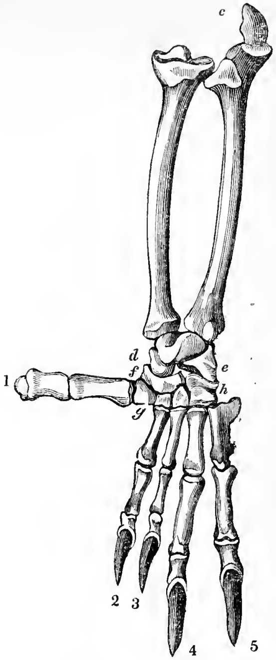
The *tibia* (*a*, *fig*. 111) presents the usual disposition of the articular surface for the condyles of the femur, but in some genera, as the Wombat and Koala, the outer articular surface is continuous with that for the head of the fibula. In the Kangaroos and Potoroos the anterior part of the head is much produced, and in the young animal its ossification commences by a centre distinct from the ordinary proximal epiphysis of the bone. A strong ridge is continued down from this protuberance for about one-sixth the length of the tibia. In the Koala a strong tuberosity projects from the anterior part of the tibia at the junction of the upper with the middle third. In this species and in the Wombat, as also in the Opossums, Dasyures, Phalangers, and Petaurists, the shaft of the tibia is somewhat compressed and twisted; but in the Kangaroos, Potoroos, and Perameles the tibia is prismatic above and subcylindrical below. The internal malleolus is very slightly produced in any Marsupial, but most so in the Wombat.

The *fibula* is complete, and forms the external malleolus in all the Marsupials. In one species of *Hypsiprymnus* and in one species of *Perameles (P. lagotis)* it is firmly united to the the lower part of the tibia, though the line of separation be manifest externally. In a second species of each of the above genera it is in close contact with the corresponding part of the tibia, but can be easily separated from that bone. In the Great Kangaroo the fibula is also a distinct bone throughout, but it is remarkably thinned and concave at its lower half, so as to be adapted to the convexity of the tibia, with which it is in close contact and attachment. In each of these genera, therefore, in which locomotion is principally performed by the hinder extremities, we perceive that their osseous structure is so modified as to ensure a due degree of fixity and strength; while in the other marsupial genera, as *Phascolarctos*, *Phascolomys*, *Phalangista*, *Petaurus*, *Didelphis*, and *Dasyurus*, the tibia and fibula are so loosely connected together and with the tarsus, that the foot enjoys a movement of rotation analogous to the pronation and supination of the hand. This property is especially advantageous in the Petaurists, Phalangers, Opossums, and Koala, because in these the inner toe is so placed and organized as to perform the office of an opposable thumb, whence these Marsupials have been termed *Pedimana* or foot-handed (*fig.* 111).

It is to this prehensile power that the modifications of the fibula chiefly relate. In the Wombat, Koala, Petaurists, and Phalangers it expands to nearly an equal size with the tibia at the distal extremity, and takes a large share in the formation of the tarsal joint; but the articular surface is slightly convex, while that of the tibia is slightly concave. The proximal extremity of the fibula is also much enlarged, but compressed and obliquely truncated, and giving off two tuberosities from its exterior surface; to the superior of these a large sesamoid bone (*c*, *fig.* 111) is articulated; I have observed the same sesamoid attached to the upper end of the fibula in a *Dasyurus macrurus* and *Petaurus taguanoides*. M. Temminck figures it in the *Didelphys ursina* and *Didelphys Philander*. This sesamoid and the expanded process to which it is attached form the analogue of the olecranon; and the correspondence of the fibula with the ulna is very remarkably maintained in the *Pet. taguanoides*, in which the proximal articular surface of the fibula is divided into two facets, one playing upon the outer condyle of the femur, the other concave, vertical, and receiving an adapted convexity on the outer side of the head of the tibia, which rotates thereupon exactly like the radius in the lesser sigmoid cavity of the ulna.

In the scansorial and gradatorial Marsupials the bones of the hinder and fore extremities are of nearly equal length, but in the saltatory species the disproportion in the development of the bones of the hind leg is very great, especially in the Kangaroos and Potoroos (*fig.* 103). However, in those singular species of *Hypsiprymnus* which inhabit New Guinea and take refuge in trees, the organization of the Kangaroo is modified and adapted so as to make climbing a possible and easy action. The fore and hind legs are here more equally developed, and the claws on the two larger toes of the hind feet are curved instead of straight. In a skeleton of one of these scansorial Potoroos, the *Hypsiprymnus ursinus*, in the Museum at Leyden, in which the humerus is three inches and a half long, the femur does not quite equal five inches in length: the ulna is nearly four inches, the fibula nearly five inches in length. The fibula is also less firmly connected with the tibia than in the great Kangaroo.

Fig. 111.



Bones of the leg and foot, Phalangista.

The following is the structure of the tarsus in the Wombat. The *astragalus* is connected as usual with the tibia, fibula, calcaneum, and scaphoides. The upper articular surface for the tibia is as usual concavo-convex, the internal surface for the inner malleolus flattened and at right angles with the preceding, but the outer articular surface presents a triangular flattened form, and instead of being bent down parallel with the inner articular surface, slopes away at a very open angle from the upper surface, and receives the articular surface of the fibula so as to sustain its vertical pressure. A very small proportion of the outer part of the inferior surface of the astragalus rests upon the calcaneum: a greater part of the superincumbent pressure is transmitted by a transversely extended convex anterior surface to the scaphoid and cuboid bones. This form of the astragalus is also characteristic of the Koala, Petaurists, Dasyures, and the Pedimanous Marsupials (*d, fig.* 111). In the Kangaroos, Potoroos, and Perameles which have the *pedes saltatorii*, the fibular articular surface of the astragalus is bent down as usual at nearly right angles with the upper tibial surface.

The *calcaneum* in the Wombat presents a ridge on the outer surface which serves to sustain the pressure of the external malleolus which is not articulated to the side of the astragalus. The internal surface which joins the astragalus is continuous with the anterior slightly concave surface which articulates with the cuboides. The posterior part of the bone is compressed, it projects backwards for nearly an inch, and is slightly bent downwards and inwards. This part is relatively shorter in the Koala, Phalangers, Opossums, and Petaurists, but it is as strongly developed in the *Dasyuri* as in the Wombat. The anterior part of the calcaneum of the Phalangers is shown at *e, fig.* 111.

In the *Dasyurus macrurus* I observe a small sesamoid bone wedged in between the astragalus, tibia, and fibula at the back part of the ankle-joint. In the *Petaurus taguanoides* there is a supplemental tarsal bone wedged in between the naviculare and cuboides on the plantar surface. In the hand-like foot of the Phalanger the structure of the tarsus is shown in *fig.* 111: *f* is the naviculare, *g* the internal cuneiform, and *h* the os cuboides. In the Wombat the scaphoid, cuboid, and three cuneiform bones have the ordinary uses and relative positions.

The analogy of the carpal and tarsal bones is very clearly illustrated in this animal. The anchylosed *naviculare* and *lunare* of the hand correspond with the *astragalus* and *naviculare* of the foot, transferring the pressure of the *facile majus* upon the three innermost bones of the second series. The long, backward-projecting *pisiform* bone of the wrist closely resembles the posterior process of the *os calcis;* the articular portion or body of the *os calcis* corresponds with the *cuneiforme* of the carpus; the large carpal *unciform* represents the tarsal *cuboides*, and performs the same function, supporting the two outer digits; the three *cuneiform* bones of the foot are obviously analogous to the *trapezium, trapezoides,* and *os magnum.* The internal cuneiform bone is the largest of the three in the Wombat, although it supports the smallest of the toes. It is of course more developed in the Pedimanous Marsupials, where it supports a large and opposable thumb.

In the Wombat the metatarsals progressively increase in length and breadth from the innermost to the fourth; the fifth or outermost metatarsal is somewhat shorter but twice as thick, and it sends off a strong obtuse process from the outside of its proximal end. A corresponding process exists in the Phalangers (*fig.* 111). The innermost metatarsal of the Wombat (*fig.* 105) supports only a single phalanx; the rest are succeeded by three phalanges each, progressively increasing in thickness to the outermost; the ungueal phalanges are elongated, gently curved downwards, and gradually diminish to a point.

In the Myrmecobius the tibial or innermost toe is represented by a short rudimental metatarsal bone concealed under the skin. In the Dasyures the innermost toe has two phalanges, but it is the most slender and does not exceed in length the metatarsal bone of the second toe. In the Petaurists it is rather shorter than the other digits but is the strongest, and in *Petaurus taguanoides* the terminal phalanx is flattened and expanded; the toes are set wide apart in this genus. In the Opossums and Phalangers the innermost metatarsal bone is directed inwards apart from the rest, and together with the first phalanx is broad and flat. The second phalanx in the Opossums supports a claw, but in the Phalangers is short, transverse, unarmed, singularly expanded in *Ph. Cookii*, but almost obsolete in *Ph. ursina* (*fig.* 111, 1). In all the preceding genera there are two small sesamoid bones on the under side of the joints of the toes, both in the fore and hind feet.

The commencement of a degeneration of the foot which is peculiar to and highly characteristic of the Marsupial animals may be discerned in the Petaurists, in the slender condition of the second and third toes, as compared with the fourth and fifth. In the Phalangers this diminution of size of the second and third toes, counting from the hallux, is more marked. They are, also, both of the same length and have no individual motion, being united together in the same sheath of integument as far as the ungueal phalanges, whence the name of *Phalangista* applied to this genus (*fig.* 111, 2 and 3).

In the saltatorial genera of Marsupials the degradation of the corresponding toes is extreme, but though reduced to almost filamentary slenderness they retain the usual number of phalanges, and the terminal one of each is armed with a claw. These claws being the only part of the rudimental digits which project freely beyond the integument, they look like little appendages at the inner side of the foot for the purpose of scratching the skin and dressing the fur, to which offices they are exclusively designed. The removal of the innermost toe, corresponding with our great toe and the hallux of the *Pedimana*, commences in the Perameles. In one species I find the metatarsal bone of this toe supports only a single rudimental phalanx which reaches to the end of the next metatarsal bone, and the internal cuneiform bone is elongated. In another species the internal toe is as long as the abortive second and third toes, and has two phalanges, the last of which is divided by the longitudinal fissure characteristic of the ungueal phalanges in this genus. In the *Perameles lagotis* the innermost toe is represented by a rudimentary metatarsal bone, about one-third the length of the adjoining metatarsal.

In the Peophagous Marsupials no rudiment of the innermost toe exists. The power of the foot is concentrated in all these genera on the fourth and fifth or two outer toes, but especially the fourth, which, in the Great Kangaroo, is upwards of a foot in length, including the metatarsal bone and the claw. This formidable weapon resembles an elongated hoof, but is three-sided and sharp-pointed like a bayonet, and with it the Kangaroo stabs and rips open the abdomen of its assailant: with the anterior extremities it will hold a powerful dog firmly during the attack, and firmly supporting itself behind upon its powerful tail, deliver its thrusts with the whole force of the hinder extremities.

The cuboid bone which supports the two outer metatarsals is proportionally developed. The internal cuneiform bone is present, though the toe which is usually articulated to it is wanting. It is also the largest of the three, and assists in supporting the second metatarsal; posteriorly it is joined with the navicular and external cuneiform bones, the small middle cuneiform occupying the space between the external and internal wedge-bones and the proximal extremities of the two abortive metatarsals. The great or fourth metatarsal is straight and somewhat flattened; the external one is compressed and slightly bent outwards; the toe which this supports is armed with a claw similar to the large one, but the ungueal phalanx does not reach to the end of the second phalanx of the fourth toe, and the whole digit is proportionally weaker.

In the climbing Potoroos, (*Hypsiprymnus ursinus* and *Hypsiprymnus dorcocephalus*), the two outer toes are proportionally shorter than in the leaping species, and are terminated by curved claws by which they gain a better hold on the branches and inequalities of trees.

Myology.—To give a description of the muscular system with the same detail as of the osteology of the Marsupials would not be attended with the same advantages. Modified as this system necessarily is in conformity with the various modes of locomotion in the different Marsupial genera, as running, leaping, burrowing, swimming, even flying, we should here fail to detect in these modifications so many marks illustrative of the aberrant and inferior type of structure of our present group as we have witnessed in those of the skeleton. In addition, moreover, to their physiological relations, the importance of the passive and enduring parts of the locomotive system to the zoology both of recent and extinct species, confers upon them a claim to our attention which the more perishable though more highly organised and active parts of the same system do not possess, even if a detailed myology comported with the scope and extent of the present work. The present notice, therefore, of this department of the anatomy of the Marsupialia will be limited to a brief description of a few of the most striking peculiarities.

Every one knows that the erect position is the most usual one in the Kangaroos; yet the conditions of this posture are very different from those in the human subject. The trunk, instead of resting on two nearly vertical pillars so placed with reference to the superincumbent weight that it rather inclines to topple forwards, is here swung upon the femora as upon two springs, which descend from the knee-joints obliquely backwards to their points of attachment at the pelvis; and the trunk is propped up behind by the long and powerful tail (*fig.* 103).

In Man the massive and expanded muscles which find their attachment in the broad bones of the pelvis, especially at the posterior part, are the chief powers in maintaining the erect posture. But in the Kangaroo the *glutæi* offer no corresponding predominance of size; the narrow prismatic ilia could not, in fact, afford them the requisite extent of fixed attachment.

The chief modifications of the muscular system in relation to the erect position of the trunk in the Kangaroo are met with on the anterior part of the base of the spinal column. The *psoæ parvæ*, for example, present proportions the very reverse of those which suggested their name in human anatomy. They form two thick, long, rounded masses, which take their origin, fleshy, from the sides of the bodies and base of the transverse processes of the lower dorsal and all the six lumbar vertebræ, and from the extremities of the three last ribs; the fibres converge penniformwise to a strong, round, middle tendon, inserted in the well-marked tubercle or spine of the pubis, already noticed.

The disposition of the abdominal muscles, especially at the pubic and hypochondriac regions, has been described and figured by Mr. Morgan* and Professor Vrolik† in the female Kangaroo. The principal modifications are seen first in the presence of a large muscle called the *triangularis* by Tyson, the *anterior rectus abdominis* by Mr. Morgan,‡ and considered as the analogue of the *pyramidalis* muscle by Meckel; secondly, in the equal development of the cremaster in both sexes; and thirdly, in the formation of a moveable bone in the situation and, as it were, in the substance of the mesial or internal pillar of the abdominal ring, which bone serves as a trochlea or pulley for the cremaster, and affords an extensive attachment to the abnormally developed *pyramidalis*.

This part of the muscular system is here described as it exists in a male Phalanger (*fig.* 112), that sex being chosen, because most of the peculiarities, as the extensive pyramidalis,§ the cremaster, and the ossified tendons of the external oblique abdominal muscle have been regarded as being essentially connected with the physiology of the marsupial pouch, whereas they are equally developed in both sexes.

The *external oblique (obliquus externus)*, besides the usual origin by digitations from the ribs, also arises from the *fascia lumborum*; it is inserted fleshy into the summit of the mar-

* Linn. Trans. xvi. 1833.

† Tydschrift voor de Natural, 1837.

‡ A portion of the external oblique is included by Mr. Morgan with the triangularis under this term.

§ Considered by Home as a sling by which the mammæ were supported.

Abdominal muscles, Phalangista vulpina.

supial bone *(a)*, over which its strong inner tendon is spread; the external oblique becomes aponeurotic at a line continued from the marsupial bone outwards, with a gentle curve, towards the anterior extremity of the ilium; and in the opposite direction, or inwards, the carneous fibres of the external oblique terminate in an aponeurosis along a line parallel with the oblique outer margin of the pyramidalis; the fascia continued from the latter boundary of the fleshy fibres passes over, or dermad of, the so-called pyramidalis, and meets its fellow at the linea alba; it is strictly analogous to the anterior layer of the sheath of the rectus in ordinary Mammalia. It is seen reflected from the *pyramidalis*, at *b*, *fig.* 112. The aponeurosis continued from the external and inferior boundary of the carneous fibres divides as usual into two distinct portions; one, corresponding to the internal or mesial pillar of the abdominal ring, spreads its glistening fibres, as above described, over the dermal surface of the marsupial bone *(c)*, to which it closely adheres: the other column *(d)* contracts as it descends obliquely inwards, forms, like Poupart's ligament, the upper boundary of the space through which the psoas and iliacus muscles and femoral vessels and nerves escape from the pelvis, and is finally inserted, thick and strong, into the outer end of the base of the marsupial bone.

This bone is so connected with the pubis that its movements are almost limited to directions forwards and backwards, or those concerned with the dilatation and diminution of the abdominal space; the contraction of the abdominal muscles must draw the bones inwards so as to compress the contents of the abdomen, and so far as the connections of the bone permit, which is to a very trifling degree, the external oblique may draw it outwards towards the ilium.

In some Marsupials, as the Koala, the triceps adductor femoris sends a slip of fibres to the external angle of the base of the marsupial bone, and would more directly tend to bend that bone outwards.

The upper or anterior fibres of the *internal oblique* have the usual origin; the lower ones *(e)* arise fleshy from the outer and anterior spine of the ilium, and for an inch along an aponeurotic chord extended from that process to the upper part of the acetabulum: these carneous fibres pass inwards, and slightly upwards, and terminate close to the outer margin of the rectus, where they adhere very strongly to the transversalis, but give off a separate sheet of thin aponeurosis which is lost in the cellular sheath of the posterior rectus.

The fleshy fibres of the *transversalis abdominis (f)* are closely connected by dense cellular tissue with those of the internal oblique; they are arranged in finer fasciculi, and have, as usual, a more transverse direction; they terminate along the same line as those of the internal oblique in an aponeurosis *(g)*, which is continued along the inner or central surface of the posterior rectus to the median line. The lower boundary of the fleshy fibres of the transversalis is parallel with the line extended transversely between the anterior extremities of the ilia; a fascia, less compact than an aponeurosis, is continued downwards from this margin, and envelopes the cremaster and the constituents of the spermatic chord, as they pass outwards and forwards beneath the lower edge of the internal oblique.

The *pyramidalis (h)* arises from the whole inner or mesial margin of the marsupial bone, from which the fibres diverge, the lower ones passing transversely across the interspace of the bones, and meeting at a very fine raphé, or linea alba; while those fibres from the anterior ends of the marsupial bones gradually exchange their transverse direction for one obliquely forwards. The breadth of each pyramidalis opposite the upper end of the marsupial bone is more than an inch, the thickness of the muscle one line.

The *rectus abdominis* or posterior rectus (*i*) comes off from the pubis along the inner part of the strong ligamentous union of the broad base of the marsupial bone, and expands as it ascends until it attains the level of the ensiform cartilage, when the rectus diminishes as it is inserted into the sternal extremities of the ribs reaching to the manubrium sterni and first rib in the Dasyures, as in the cats.

The slight indications of tendinous intersections which were noticed in this dissection were confined to the posterior or central superficies of the muscle; the first extended only half-way across from the outer margin.

The *cremaster* (*k*), in the Phalanger and Opossum, is not a fasciculus of fibres simply detached from the lower margin of the internal oblique or transversalis, but arises by a narrow though strong aponeurosis from the ilium, within and a little above the lower boundary of the internal oblique, with the fibres of which the course of the cremaster is not parallel; it might be considered as a part of the transversalis, but it is separated by the fascia above mentioned from the carneous part of that muscle. Having emerged from beneath the margin of the internal oblique, the cremaster escapes by the large elliptic abdominal ring (*l*), bends round the marsupial bone near its free extremity, and expands upon the *tunica vaginalis testis*. In the female it has the same origin, course, and size, but spreads over the mammary glands at the back of the pouch. If the anterior fascicles of the diverging and embracing fibres be dissected from the posterior ones, the appearance of the cremaster dividing into two layers is produced.

The principal modifications of the muscles of the pectoral extremity are here described as they exist in the *Perameles lagotis*.

The *trapezius* is a broad and very thin muscle, having its origin extended from the skull, along the cervical and dorsal spines, to the fascia covering the lumbar portion of the latissimus dorsi: its fibres converge to be inserted along the spine of the scapula, the anterior ones directly continued into the pectorales, whereby it becomes an extensor of the humerus and a protractor of the fore extremity.

The *latissimus dorsi* arises chiefly from the broad aponeurosis covering the muscles of the lumbar region of the spine, and from the spines of the six posterior dorsal vertebræ; the fibres gradually converge, the muscle increasing in thickness as it diminishes in breadth, and terminating in a strong flattened tendon one inch before its insertion at the upper third of the humerus.

The chief peculiarity of this muscle is its connection with an accessory extensor (*omo-anconeus*) of the antibrachium. This extensor takes its principal origin by fleshy fibres from the terminal half inch of the fleshy part of the latissimus dorsi, and continues fleshy, slightly diminishing in size to its insertion at the apex of the olecranon; it may thus be considered as a slip detached from the latissimus dorsi, yet its fibres from their very origin run at right angles to those of that muscle, to which they are attached. To remedy the inconvenience of an origin from a yielding and flexible part, a thin aponeurotic slip, two lines in breadth and an inch in length, attaches a part of the base of the superadded muscle and the corresponding portion of the latissimus dorsi to the sheath of the teres major, and to the inferior costa of the scapula near its posterior angle.

The *serratus magnus* offers no peculiarity worthy of notice.

The *supra-spinatus*, a strong penniform muscle, exceeds the *infra-spinatus* in breadth by as much as the supra-spinal fossa is broader than the infra-spinal one: it has a broad and strong insertion into the great outer tuberosity of the humerus. The *infra-spinatus* is inserted into the upper and posterior part of that tuberosity.

The *deltoides* is a comparatively small muscle; it arises from the anterior half of the spine of the scapula and from a fine aponeurosis covering the infra-spinatus; its fibres converge to be inserted in the upper part of the deltoid ridge.

A thin small strip of muscle arises from about the middle of the inferior costa of the scapula, beneath the infra-spinatus; its fibres pass forwards and join the lower margin of the small deltoid, thus bracing and enclosing the tendon of the infra-spinatus.

The *subscapularis* offers no peculiarity.

The *teres major* is a strong sub-compressed muscle arising from near the posterior half of the inferior costa of the scapula, and joining, as before stated, the tendon of the latissimus.

The *triceps extensor* has its long portion arising from the anterior third of the inferior costa of the scapula; its second head comes from the posterior part of the proximal third of the humerus; the third portion takes its origin from the whole of the posterior part of the humerus; in addition to these, the olecranon receives the above described fourth superadded slip from the latissimus dorsi.

The *pectoralis major* is, as usual in the Marsupial and many of the Placental quadrupeds, a very complicated muscle; it consists of an anterior or superficial, and a posterior or deeper portion; the anterior portion receives the strip of fibres before mentioned from the trapezius, there being no clavicle or clavicular ossicle interposed in the Perameles: its fibres converge, increasing in thickness as they diminish in breadth, and are inserted into the anterior and outer part of the strongly developed pectoral ridge. The second and main portion of the pectoralis arises from the whole extent of the sternum; its fibres are twisted obliquely across each other as they converge to be inserted into the inner part of the pectoral ridge; some of the internal and posterior fibres of this portion of the twisted pectoral pass obliquely upwards and behind the anterior fasciculi, and are inserted into the coracoid process, thus representing the pectoralis minor.* Beneath this latter portion of the twisted pectoral, a long and slender muscle passes to be inserted into the anterior part of the tuberosity of the humerus; this may likewise be regarded as a dismemberment of the pectoralis major, but it arises from the fascia of the rectus abdominis, below the cartilages of the lower ribs. Thus the strong pectoral ridge of the humerus is acted upon by muscles having a range of origin from the occiput and cervical vertebræ along the whole extent of the chest to the beginning of the abdomen.

The *biceps* is a powerful muscle, although its short head from the coracoid process is suppressed. The long head has the usual origin and relation to the shoulder-joint; its tendon is very thick and short. The fleshy belly joins that of the strong brachialis internus, situated at the external side of the humerus, whence it takes its principal origin from the short deltoid ridge, closely connected there with the second portion of the triceps, and deriving some fleshy fibres from the lower and outer third of the humerus. The portion of the biceps arising by the long head soon resolves itself into two distinct penniform muscles; the tendon of the outer one joins that of the brachialis, and this conjoined tendon simply bends the fore-arm,

* Professor Vrolik found that the pectoralis minor in the Kangaroo was inserted not into the coracoid process, but into the humerus between the biceps and the tendon of the pectoralis major.

while the other tendon bends and pronates; this, which is a direct though partial continuation of the biceps, is inserted into the ordinary tubercle of the radius; whereas the other tendon is attached to the fore part of the proximal end of the ulna.

The muscles which arise from the internal condyle of the humerus are the *pronator teres*, which has the usual origin, insertion, and relative proportions, and next the *palmaris longus*.

There are, likewise, distinct and strong fasciculi of muscles corresponding to the *flexor carpi ulnaris* and *radialis*, and to the *flexor sublimis digitorum*.

The strong ridge continued from the olecranon to the posterior and inner part of the ulna gives origin to a great proportion of the oblique fibres of the *flexor profundus;* but both this and the *flexor sublimis* terminate in a single thick and strong tendon, which after passing the wrist divides into those corresponding with the perforating and perforated tendons here concentrated upon the three long middle fingers.

The *pronator quadratus* runs the whole length of the interosseous space, passing from the radius a little obliquely downwards to the ulna.

The *supinator longus*, arising as usual from the upper part of the strongly developed ridge above the outer condyle, sends its tendon across the carpal joint, which tendon divides before it crosses, and is inserted by one of its divisions into the base of one of the metacarpal bones of the index finger, and the other to the adjoining metacarpal bone.

These are the principal muscles of the fore extremity which require notice in this place. Their modifications, in respect of number and strength, relate to the act of digging up the soil, which is habitual in the Bandicoots, as it is for the purpose of obtaining food, and not for shelter. It is for this purpose that the three middle digits of the hand are developed at the expense of the other two, which are rudimental; and we have seen that the whole power of the deep and superficial flexors is concentrated upon the fossorial and well-armed fingers; and that by the single common tendon in which the fleshy fibres of these muscles terminate, they move them collectively and simultaneously. Thus variety of application, and especially the prehensile faculty, are sacrificed to the acquisition of force for the essential action. In no Marsupial is the hand so cramped as in the *Perameles*, excepting in the *Chœropus*, where the functional and fossorial fingers are reduced from three to two. It is in relation to this condition, doubtless, that the clavicles are wanting in these genera, while all other Marsupials possess them. The inverted position of the pouch in the Perameles might also be conceived to have relation to their imperfect hands, the mouth of the pouch being thus brought nearer to the vulva; but I am disposed to regard it as being more essentially connected with the habitually inclined or procumbent position of the trunk in the Saltatorial Entomophaga.

The muscles of the hinder extremity are chiefly remarkable in the Kangaroo for their prodigious strength and unusual number: the accessory muscle of the biceps, e. g. is divided into two strong fasciculi, which unite to be inserted into the side of the patella;* the pyriformis is also a double muscle.†

The *sartorius* has its insertion so modified that it becomes an extensor instead of a flexor of the tibia: it is chiefly fixed to the tibial side of the patella, and by fascia into the capsular ligament of the knee-joint and the anterior proximal tuberosity of the tibia. In a Dasyure (*Das. macrurus*) I found that the sartorius had a similar disposition and office. In this ambulatory carnivorous Marsupial the *external* and *middle glutæi* are so disposed as to extend the thigh, while the *internal glutæus* inflects and rotates it inwards.

In a Bandicoot (*Perameles lagotis*) the *sartorius* ran nearly parallel with and dermad of the *rectus*, and was inserted into the upper part of the patella. Besides this sesamoid, which is rarely developed in other Marsupials, I found a thick cartilage attached to its upper part and interposed between the common tendon of the recti and vasti, removing that tendon further from the centre of motion and increasing the power of the extensor muscles of the leg.

The *rectus femoris* has its two origins very distinct, and its analogy to the biceps of the upper extremity is very close. The *gracilis* is a very thick and strong muscle.

The *biceps flexor cruris* in the Perameles is a muscle of very great strength; it terminates in a strong and broad aponeurosis, which extends over the whole anterior part of the tibia, being attached to the rotular tuberosity of that bone, and terminating below in the sheath of the tendo Achillis, whereby this muscle becomes an extensor of the foot.

It is a curious fact that all the equipedal Marsupials, whether burrowers as the Wombat, climbers as the Koala, Phalangers, and Opossums, or simply gressorial, as the *Dasyuridæ*, have the *tibia* and *fibula* so connected together as to allow of a certain degree of rotation upon each other, analogous to the pronatory and supinatory movements of the bones of the antibrachium, and the muscles of the leg present corresponding modifications. It is not without interest in the question of the affinities of the Marsupials to find that none of the analogous carnivorous, pedimanous, or rodent Placentals present this condition of the hind leg.

In the *Dasyurus macrurus*, the *plantaris*, instead of rising from the femur, has its fixed point in the fibula, from the head to half-way down the bone, fleshy; its tendon passes obliquely inwards and glides behind the inner malleolus to its insertion in the plantar fascia, so that it rotates the tibia inwards besides extending the foot. The *soleus* has an extensive origin from the proximal to near the distal end of the fibula. There are as usual three deep-seated muscles at the back of the leg. Of these three the muscle analogous to the *tibialis posticus* is readily recognized; its tendon glides

* Cuvier, loc. cit. p. 501.
† Ibid. p. 502.

behind the inner malleolus, and is inserted into the inner or tibial cuneiform bone.

The muscle which has the relative position and origins of the *flexor longus pollicis*, sends its tendon by the usual route to the sole of the foot, where it divides and distributes a flexor tendon to all the toes except the rudimental hallux; it has the same disposition in the Opossums, where the hinder thumb or great toe is fully developed; for this modification, however, the Comparative Anatomist is already prepared by meeting with it in the first step from man, viz. in the Chimpanzee and Orang.*

The third deep-seated muscle, being situated internal to the two preceding ones, may be the analogue of the *flexor digitorum communis longus;* it nevertheless sends no tendon to the toes nor even to the tarsus, but its fibres pass from the tibia obliquely outwards and downwards between the preceding muscle and the interosseous ligament to the fibula, where they are exclusively inserted so as to oppose the plantaris and rotate the foot outwards. This muscle closely adheres to the interosseous fascia, and thus resembles in its attachments the pronator quadratus of the fore limb: it is most developed in the pedimanous climbing Marsupials, where the rotation of the foot is more extensive and more useful.

The subjoined illustration (*fig.* 113) of this modification of the muscles of the hind-foot is taken from a dissection of the *Phalangista vulpina*, which very closely accords with that above described in the *Dasyurus macrurus: a*, expanded tendon of the *sartorius; b, gracilis; c, semitendinosus;* and *d, semi-membranosus;* both these muscles are inserted, as in many other quadrupeds, low down the tibia: *e, gastrocnemius; f, plantaris; g*, the analogue of the *flexor longus pollicis pedis; h, tibialis posticus;* this muscle divides and is inserted by two tendons, *h'* and *h''*, into the internal and middle cuneiform bones: *i*, the rotator muscle of the tibia, probably a modification of the *flexor digitorum communis pedis;* its fibres descend obliquely from the fibula *p* to the tibia *t*.

In the muscles on the anterior part of the leg I observed no peculiarity worthy of notice; the *extensor brevis digitorum* has, however, its origin extended into this region and is attached to the outside of the fibula. There are three *peronei;* the external one is inserted into the proximal end of the fifth metatarsal: the tendon of the middle peroneus crosses the sole in a groove of the cuboid like the peroneus longus: the internal peroneus is an extensor of the outer or fifth toe. The *Perameles lagotis*, among the Saltatorial Marsupials, presents a different condition of the extensors of the foot from that above described. The *gastrocnemii, soleus*, and *plantaris* all arise above the knee-joint, and the tendon of the plantaris, after sheathing the tendo Achillis and traversing the long sole, is finally inserted into the base of the metatarsal bone of the fourth or largest toe; thus this muscle, which is strongly developed, bends both this toe and the knee, while it extends the foot.

* Zoolog. Proceedings, 1830, p. 59.

Fig. 113.

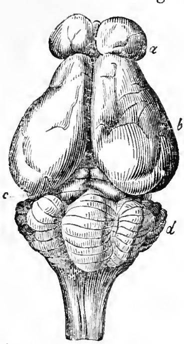
Muscles of leg, Phalangista vulpina.

Nervous System.

The *brain* bears a smaller proportion to the body in the Marsupials than in any other order of Mammals: thus, in the Ursine Dasyure it is as 1 to 520, in the Wombat as 1 to 614, in the great Kangaroo as 1 to 800: it is relatively largest in the smaller species of Petaurists and Phalangers.

The Marsupial brain is also the simplest as respects its external form in the Mammiferous class. The cerebral hemispheres do not extend over the cerebellum in any of the species, and in some, as the Dasyures and Opossums, they leave the optic lobes exposed. The brain consists, as in other Mammalia, of a medulla oblongata with a pons Varolii, cerebellum (*d*, *fig.* 114), optic lobes, or bigeminal bodies, (*c*, *fig.* 114), cerebrum (*b*), to which may be added, on account of their large proportional size and distinct development, the olfactory lobes (*a*, *a*,). In the Phalangers and Petaurists, the Opossums, Perameles, the insectivorous Phascogales, and the smaller Dasyures the surface of the cerebral hemispheres is smooth and unconvoluted. In the *Dasyurus ursinus* the complication of the cerebral surface is merely indicated by a few slight indentations; it is in the strictly herbivorous species as the Kangaroo (*fig.* 115) and Wombat, that the

Fig. 114.

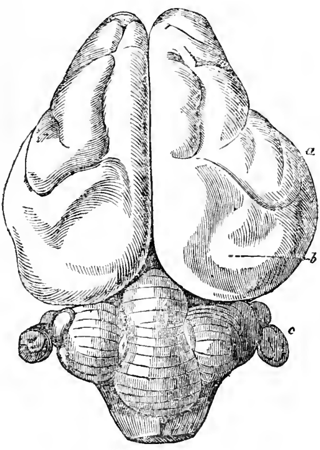


Brain of Dasyurus ursinus.

hemispheres are penetrated by anfractuous fissures.

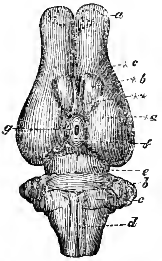
In the Wombat a large longitudinal fissure bounds the outer side of the natiform protuberance and olfactory tract at the base of the brain; from the anterior moiety of this fissure three or four smaller ones curve upwards upon the sides of the hemispheres. On the upper surface a short transverse fissure marks off what may be regarded as the anterior lobe of the cerebrum, and behind this each hemisphere exhibits a few detached shallow fissures. In the Kangaroo (*fig.* 115) these fissures become continuous and are deeper; a long and nearly transverse anfractuosity divides the upper surface of the hemisphere; behind the shorter fissure which marks off the anterior lobe, and between the two transverse fissures there is a longitudinal one bounding a convolution that runs parallel with the median interspace of the hemispheres. The anterior lobes are also broken by small fissures; two or three long and moderately deep ones ascend upon the sides of the hemispheres (*a*), and the posterior portion (*b*) presents occasionally small detached fissures. So far therefore as the external surface is concerned, the brains of the herbivorous Marsupials are more complicated than those of any of the Rodent Mammalia. The cerebellum presents the usual close-set, sub-parallel, transverse convolutions: it is remarkable for the large proportional size of the median or vermiform lobe, as compared with the lateral lobes, especially in the carnivorous and insectivorous Marsupials, where this condition is associated with a corresponding diminution of their commissural band or 'pons Varolii,' as is shown in the view of the base of the brain of an Opossum (*fig.* 116, *b*).

Fig. 115.



Brain of Macropus major.

Fig. 116.



Brain of Didelphys Virginiana.

In the Kangaroos, Perameles, Phalangers, and Koala the hemispheres or lateral lobes of the cerebellum are characterized by a small subspherical lateral process or appendage (*c*, *c*, *fig.* 115), which is lodged in a peculiar fossa of the petrous bone above the internal meatus: there are corresponding but less produced processes in the Dasyures and Opossums, but they are not developed in the Wombat. On the upper surface of the cerebellum the medullary substance appears superficially at a small tract between the vermiform processes, marked with an asterisk in figures 115 and 117. The simple disposition of the arbor vitæ is shown in *fig.* 118, *f.* Behind the pons Varolii are seen the two trapezoid bodies (*c*, *fig.* 116); and the corpora pyramidalia (*d*) are always clearly distinguishable from the corpora olivaria. The *crura cerebri*, which, in the Opossum (*e*, *fig.* 116) are left exposed below, like the optic lobes above, by reason of the small proportional size of the cerebrum, are more completely concealed in the brain of the Kangaroo and Wombat. The natiform protuberances form a great proportion of the under part of the cerebral hemispheres in all the Marsupials; their external boundary, which is basial in the Wombat and Kangaroo, runs along the side of the hemispheres to the outer side of the olfactory lobe in the Opossum. The inner root of the olfactory nerve forms a bulbous or ganglionic enlargement (*fig.* 116, * *b*). Behind the commissure of the optic nerves is seen a broad and short infundibulum supporting the pituitary gland (*d*, *fig.* 118), and posterior to this is the single corpus albicans. The optic lobes are solid, and are each divided by a transverse fissure, as in the Placental Mammalia; the anterior divisions or 'nates' (B, *fig.* 117) have a greater longitudinal diameter than the posterior ones or 'testes,' which have a greater transverse development.

The difference in the relative development of the nates and testes is much less in the herbivorous and carnivorous Marsupials than in the corresponding Placental quadrupeds.

From the fact that the cerebral organ is that which exhibits the most marked degradation of structure in the class of warm-blooded Vertebrate animals which are characterized by an oviparous generation, I was induced to suspect, after having ascertained how closely the Marsupialia approached Birds in their mode of generation, that the brain might present in them some corresponding inferiority of structure, as compared with the Placental Mammalia.

The brain in the placental Mammalia is essentially characterized by the complexity and magnitude of the apparatus by which the hemispheres are brought into communication with one another. With respect to size, the cerebrum is in many species proportionally inferior to that of Birds; and in most Insectivorous and Rodent Mammalia it presents an equally smooth and uniform external surface; but notwithstanding the absence of convolutions and its diminished size, a large apparatus of medullary fibres is present, which connect together the opposite hemispheres, as well as the distant parts of the same hemisphere; and this apparatus, or great commissure, is superadded to the anterior, posterior, and soft commissures, which, with the exception of a very slight rudiment of the fornix, are alone developed in Birds for the purpose of uniting the opposite sides of the brain. In the higher Mammalia, in which the cerebral hemispheres acquire superior size and increased extent of surface by means of convolutions, the superadded commissural apparatus presents a corresponding development and a highly complicated structure; its several parts being distinguished as the corpus callosum, fornix, and their intercommunicating laminæ, termed the septum lucidum.

The corpus callosum is the principal bond of union between the opposite hemispheres; it extends, as is well known, horizontally above the ventricles, its middle fibres passing transversely, while those of its extremities, which are more or less bent beneath its body, radiate, and all intermix, in apposition with the ascending and diverging fibres of the peduncles of the cerebral hemispheres. It has hitherto been considered as the great characteristic of the brain in the Mammalia, and, taking the human brain as the term of comparison, to be developed in the ratio of the magnitude of the cerebral hemispheres.

In the placental Mammalia this is a pretty accurate expression of the relations of the corpus callosum; and as the posterior lobes of the hemispheres are the first to disappear in the descending comparison, so the corpus callosum diminishes in longitudinal extent from behind forwards, and thus the corpora quadrigemina, pineal gland, and posterior part of the optic thalami are successively brought into view on divaricating the cerebral hemispheres in the different Mammalia, as the Rodentia, Cheiroptera, and Edentata, which exhibit this progressive degradation of the great commissure.

An attentive study of the manners of different Marsupials in confinement, and an inspection of the exterior forms of the brain in some of the species, induced me to allude, in my paper on the generation of the Kangaroo,* to an inferiority of intelligence and a low development of the cerebral organ, as being the circumstances in the habits and structure of these singular animals, which were most constantly associated with the peculiarities of their generative economy. I have since derived the most satisfactory confirmation of this coincidence from repeated dissections of the brains of Marsupials belonging to different genera; and although unable to explain how a brief intra-uterine existence and the absence of a placental connexion between the mother and fœtus can operate (if it be really effective and any thing more than a relation of simple coexistence) in arresting the development of the brain, yet it is a coincidence which has not been suspected, and is, in various points of view, perhaps the most interesting of the anatomical peculiarities of the quadrupeds here treated of.

In order to obtain satisfactory proof of the difference in the structure of the brain in the marsupial and placental quadruped, I have dissected and compared together, step by step, the brains of a Wombat and Beaver. These animals are of nearly equal bulk, and manifest so many mutual affinities in their structure that they have been classed in the same order of Mammalia. The Wombat is, in fact, in all its exterior characters, save the marsupial and scrotal pouch, a Rodent; and in its internal anatomy, especially its digestive organs, more nearly resembles the Beaver than do many of the true Rodent animals. The brain of the Beaver was also preferred for this comparison of internal organization, because, on an outward inspection, it would be pronounced to be the less highly organized of the two; the hemispheres in the Wombat presenting a few convolutions, as before described, whilst in the Beaver they are perfectly smooth.

In the Beaver, however, the cerebrum is extended further backward, although it still leaves the cerebellum quite uncovered; while in the Wombat a portion of the optic lobes (corpora quadrigemina) is also exposed.

On divaricating the hemispheres of the brain in the Beaver we bring into view, about three lines below the surface, the corpus callosum; and on removing the cerebral substance to a level with this body, its fibres are observed to diverge into the substance of each hemisphere in the usual manner, some bending upwards, but a greater proportion arching downwards and embracing the cerebral nuclei; the anterior fibres radiating into the anterior, the posterior fibres into the posterior extremities of the hemispheres.

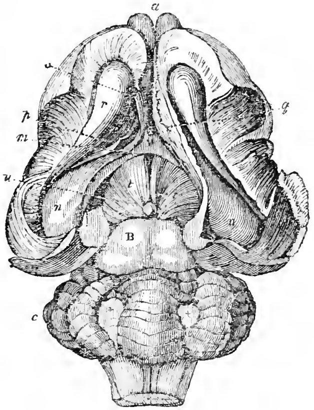
The portions of the brain which are removed in thus tracing the extent of the corpus callosum, bring into view the corpora bigemina and the pineal gland; but the optic thalami are concealed by the great commissure above described.

On separating the hemispheres of the brain of the Wombat, not only the bigeminal bodies (*B, fig.* 117,) and pineal gland (*u, fig.* 117,)

* Phil. Trans. 1334, p. 358.

but the optic thalami (*t*, *t*, *fig*. 117) are immediately brought into view, and instead of a

Fig. 117.



Phascolomys fusca.

broad corpus callosum, we perceive, situated deeply at the bottom of the longitudinal fissure, a small commissural medullary band, (*m*, *fig*. 117) passing in an arched form over the anterior part of the thalami, and extending beneath the overlapping internal or mesial surfaces of the hemispheres, (*q*, *fig*. 117,) which are thus, as in the Bird, disconnected with each other.

On gently raising the hemispheres from above the commissure and pressing them outwards with the handle of a scalpel, the instrument passes into the fissure upon which the hippocampus (*n*, *fig*. 117) is folded; and, on continuing the pressure, the hippocampus is torn through, and the lateral ventricle is exposed. The mesial wall of the hemisphere is continued from the superior and internal border of the hippocampus, and is composed in the Wombat, as in the Bird, of a thin lamina of medullary substance analogous to a detached layer of the septum lucidum. In the Kangaroo the mesial parietes of the lateral ventricles are stronger, being about two lines in thickness.

The posterior transverse fibres of the commissure are continued outwards and backwards beneath the more longitudinal fibres, which overlap them as they pass from the tæniæ hippocampi (*o*, *fig*. 117) forwards to the anterior cerebral lobes. All the fibres of the commissure pass along the floor of the lateral ventricles into the substance of the hippocampi majores, which are of proportionally very large size. Thus the commissure, which is brought into view on divaricating the cerebral hemispheres in the Wombat, is seen to be partly the bond of union of the two hippocampi majores in the transverse direction, and partly of the hippocampus and anterior lobe of the same hemisphere in the longitudinal direction. It also fulfils the other function of the fornix by sending down from the inferior surface two small nerve-like processes, which extend vertically, behind the anterior commissure, through the substance of the optic thalami, near their mesial surfaces, to the corpus albicans, at the base of the brain.

The superior view of the connexions of the hippocampal commissure of the Wombat is given at *m*, *n*, *o*, *fig*. 117.

If in the Beaver's brain the posterior thickened margin of the corpus callosum be raised, it is observed at the middle of its inferior surface to be closely connected with the centre of a commissural band of fibres, arching over the anterior part of the optic thalami, and passing outwards and backwards along the floor of the lateral ventricles into the substance of the hippocampi, which are as largely developed as in the Wombat. The anterior part of the corpus callosum is bent downwards, and is attached along the middle line of its inferior surface by a uniting medium of medullary substance, representing the septum lucidum, to the hippocampal commissure or fornix; the tæniæ hippocampi extend forwards, as in the Wombat, into the anterior lobes.

The corpus callosum being removed, and the commissural fibres of the hippocampi being left behind, the view of the Beaver's brain now corresponds with that obtained in the previous dissection of the brain of the Wombat, which we regard, therefore, as wanting the principal mass of the corpus callosum, the septum lucidum, and consequently the fifth ventricle. The artery of the plexus choroides, (*p*, *fig*. 117,) in both the Beaver and Wombat, enters the lateral ventricle, where the hippocampus commences at the base of the hemisphere, and the plexus is continued along the under surface of the tænia hippocampi, and passes beneath the fornix, through the usual foramen, to communicate with its fellow in the third ventricle immediately behind the anterior crura of the fornix, which are sent down in the Beaver, as in the Wombat, from the centre of the inferior surface of the hippocampal commissure.

If we expose the lateral ventricle by removing its outer parietes in a marsupial and placental quadruped, as, for example, in the Kangaroo and Ass, the hippocampus major, the tænia hippocampi, the plexus choroides, and the foramen Monroianum are brought into view. If a style be thrust transversely through the internal wall of the ventricle, immediately above the hippocampus, in the placental quadruped, it perforates the septum lucidum and enters the opposite ventricle below the corpus callosum. If the same be done in the marsupial brain the style passes into the opposite ventricle, but is immediately brought into view from above by divaricating the hemispheres, and is seen lying above the fornix or commissure of the hippocampi.

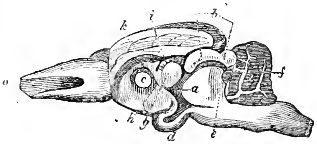
This commissure may, nevertheless, be regarded as representing, besides the fornix, the rudimental commencement of the corpus callosum; but this determination does not invalidate the fact that the great commissure which unites the supra-ventricular masses in the Beaver, the Bat, and all other placentally developed

Mammalia, and which exists in addition to the hippocampal commissure, is wanting in the brain of the Wombat; and as the same deficiency exists in the brain of the Great and Bush Kangaroos, the Vulpine Phalanger, the Perameles lagotis, the Ursine and Mauge's Dasyures, and the Virginian Opossum, it is most probably the cerebral characteristic of the marsupial division of Mammalia.

In the modification of the commissural apparatus above described, the Marsupialia present a structure of brain which is intermediate between that of the placental Mammalia and Birds; as in the latter class the great commissure is wholly wanting, and the hemispheres, though comparatively larger than in many of the Mammalia, are brought into communication only by means of the anterior, posterior, and soft commissures, and by a slight trace of the fornix or hippocampal commissure.

Of the other peculiarities of the marsupial brain, the relatively large size of the anterior commissure (*c*, *fig.* 118) is most worthy of notice; its development corresponds with the large size of the cerebral ganglion, which

Fig 118.



Didelphys Virginiana.

forms the chief origin of the olfactory nerve, and some of the anterior fibres of this commissure arch forwards, and are directly continued into those nerves.

In the position, superficial transverse fissure, and solidity of the bigeminal bodies, the marsupial brain adheres to the Mammiferous type, as also in the exterior transverse fibres of the commissure of the cerebellum, forming the pons Varolii, the presence of which relates to the development of the lateral lobes of the cerebellum.

In one of the latest published treatises on comparative anatomy, the Lehrbuch der Vergleichenden Zootomie, zweite auflage, 1834, of Carus, the first and chief structural characteristic of the brain in Mammalia is stated, as in the Leçons d'Anatomie Comparée of Cuvier, to be the presence of the corpus callosum.* The brain of the Rodentia is cited as the example of the transitional condition of this organ from Mammalia to Birds.† Besides the *Rodentia*, Carus afterwards states that the *Monotremata*, *Marsupialia*, and *Insectivora* (shrews, moles, and bats) also present the more simple form of brain among the Mammalia, "the hemispheres being of an ovate form contracted anteriorly, and their surface perfectly smooth, as in Birds, not extending over the cerebellum, and sometimes not over the corpora quadrigemina. Internally the great commissure is generally very short (in the Bats and Kangaroo hardly so long as the corpora quadrigemina, a structure which reminds one of that in Birds). The fold of the corpus callosum and the cornua ammonis (which Carus terms the processes of the corpus callosum in the ventricles) are commonly broad and large."* In illustration of this simple structure of the mammiferous brain Carus gives a figure of the brain of a Rodent, and from the whole description the reader is led to infer that the Rodent and Insectivorous placental Mammalia participate with the marsupial Mammalia in all the characters of the cerebral organization which approximate to those in Birds. Rudolph Wagner also describes the brain in the Rodentia, Cheiroptera, Edentata, and Marsupialia as being characterised by the small size of the corpus callosum,† which does not extend far back. It must not be supposed that the preceding quotations are adduced to detract from the merit of works whose reputation deservedly stands high. The position of the accomplished and indefatigable authors in a central town of Germany is unfavourable to the acquisition of specimens of animals which, like the Marsupialia, are almost confined to one of our most distant colonies; but it would be unpardonable in an English Comparative Anatomist, possessing the requisite opportunities of consulting nature, to content himself with copying the generalizations of foreign systematic writers, which, as regards the marsupial Mammalia, are liable to repose on so limited and imperfect an induction.

The Spinal Chord.—The spinal chord manifests all the usual Mammalian characters; the brachial and pelvic enlargements correspond with the relative size and muscularity of the extremities to which they furnish the nerves, the lumbar or pelvic enlargement is consequently most marked in the Kangaroo (*fig.* 119) and Potoroos, but does not exhibit the rhomboidal sinus which characterises this part of the chord in Birds. The disposition of the layer of

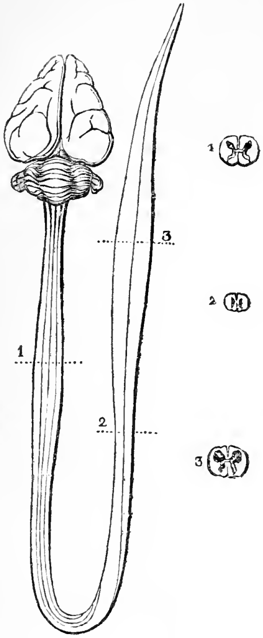
* 'Theils und vorzüglich werden sie in den durch eine neue grosse Commissur vereinigten,' § 122, B. i. p. 77. "Die einzelnen Hirnmassen betreffend, so aüssert sich, wie schon bemerkt, das Eigenthümliche der *ersten*, der Hemisphären, vorzüglich durch die Erscheinung des Balkens (corpus callosum) und des Gewölbes (fornix)."

† "Im allgemeinen bildet zur Hirnform dieser Klasse von der der vorigen (der Vögel) die Gehirnbildung, wie sie in den *Nagethieren* (Rodentia) beobachtet wird, den deutlichsten Uebergang." Ibid. p. 77.

* "Die aussere gestalt der hemisphären ist in den Nagern, so wie in den Schnabel-und Beutelthieren, Spitzmäusen, Maulwürfen und Fledermäusen ein vorwärts sich verschmälerndes Eirund, und ihre Oberfläche, wie in Vogel vollkommen glatt; hinterwärts werden dadurch weder kleines Hirn, ja oft nicht einmal die Vierhugel bedeckt; innerlich ist die grosse Commissur (corpus callosum) gewöhnlich noch sehr kurz (bei den Fledermäusen und dem Känguruh kaum so lang als die Vierhügel, eine Bildung, so an die Vögel erinnert) der Umschlag des Balkens und Forsetzung desselben in die Seitenhohlen (cornua Ammonis) vorzüglich breit und gros (f. v. e. g.)" Ibid. § 124, p. 79.

† Der Balken ist noch schmal bei den Nagern, Fledermäusen, Edentaten und Beutelthieren und geht nicht weit nach hinten.—*Lehrbuch der Vergleichenden Anatomie*, p. 609, 1835.

Fig. 119.



Brain and spinal chord, Macropus penicillatus.

grey matter enveloping the central medullary tract in each lateral moiety of the chord is shewn in the three situations marked 1, 2, and 3 (*fig.* 119); the superior expansion and complexity of the grey matter in the anterior columns of the pelvic enlargement accords with the predominance of the locomotive over the sensitive function* in the strong saltatory hind legs of the Kangaroo.

Organs of Sense.—The olfactory nerves and the osseous cavities and laminæ destined for the protection and support of the pituitary membrane offer a remarkable proportional development in all the Marsupials, and more especially in the Insectivorous and Carnivorous tribes. The outer root of the olfactory nerve appears as a continuation of the whole natiform protruberance; a corresponding accumulation of nervous matter, " protuberantia pyriformis," † at the base of the inner root of the olfactory nerve has already been noticed; both these broad tracts consist externally of grey matter: the middle or medullary root of the nerve is the smallest. It is very conspicuous in the Wombat, where it emerges from a longitudinal fissure at the anterior and inner part of the " protuberantia natiformis." The olfactory nerves or rather lobes are hollow, and contain, as in most Mammalia, the anterior continuation or extremity of the lateral ventricles (*o*, *fig.* 118). The filaments pass from the skull through several foramina of a cribriform plate. Certain species of Kangaroo, of the subgenus *Osphranter*, Gould, remarkable for their acuteness of smell, have the turbinated bones so large that the lateral expansion of the nasal cavity forms a marked feature in the skull.

The chief deviation from the Mammalian type in the *organ of hearing* presents itself in the form of the stapes, the body of which is a simple elongated style either entirely, as the Perameles, or for half its length, as in the Kangaroo (*fig.* 120), where it divides into two short crura, before terminating in the base; it thus more or less approximates to the form of the columella in the bird.

Fig. 120.

Stapes of the Kangaroo.

The largest proportional external ears are those of the *Perameles lagotis*, the shortest those of the Wombat. The internal structure of the ear is not less strikingly developed in the Perameles than the outward appendages. The tympanic cavity is very extensive, but is formed, as in other Marsupials, by the sphenoid and petrous bones; the tympanic bone is limited to the function of supporting the ear-drum, and forming the internal commencement of the meatus auditorius externus. The internal extremity of the tympanic cylinder projects obliquely into the posterior and outer part of the sphenoidal bulla. The membrana tympani is a delicate transparent tissue, slightly concave internally, and having the long handle of the malleus (*a*, *fig.* 121) attached to it. This process of the malleus is bent upon itself at a right angle; the inner portion is broader and thicker than that which is attached to the membrana tympani, and it is anchylosed at its internal extremity by a thin and transparent plate of bone (*b*) to the side of the incus (*c*). This little ossicle, which here appears as a process of the malleus, presents a notched articular surface for the orbicular end of the stapes. This portion of the stapes gives off a short slender process for the attachment of the stapedius (*d*), and then is continued in the form of a moderately long and slender columelliform shaft to the elliptical and slightly expanded base which closes the foramen ovale.

Fig. 121.

Auditory ossicles, Perameles.

Organ of Vision.—The anatomy of the eye offers no peculiarity illustrative of the affinities of the Marsupialia or of any other speciality in their economy save the nocturnal habits of the majority of the order. It is in relation to these habits that the lens is large and convex, the iris broad, the pupil round and generally wide, and the cornea correspondingly large.

The Harderian gland and the retractor oculi co-exist, as usual in Mammalia, with the nictitating eyelid. This is always largely de-

* Mayo, Outlines of Physiology, p. 235.
Phil. Trans. 1837, p. 95.

veloped, and the conjunctiva covering its free margin is stained black.

In the Kangaroo I found the dark pigment on both the inside and outside of the choroid, and the ciliary processes very well developed. The lens is proportionally large. In the dead Kangaroo the radiated muscle of the iris is much contracted, and the pupil widely open. Beneath the upper eyelid in the Kangaroo there is a cartilaginous ridge having the conjunctiva reflected over it.

Organ of taste.—The tongue is well developed and freely moveable in all the Marsupialia, and the epithelium covering the simple papillæ of its dorsum is never condensed into spines. In the carnivorous species, as the *Dasyuri,* the conical papillæ are minute and soft, but directed backwards so as to give a slight roughness to the tongue when stroked in the opposite direction. Under a lens they appear like fine shagreen. Near the base of the tongue in *Dasyurus viverrinus* there are three fossulate papillæ, in triangle, with the apex towards the epiglottis. There is a small *lytta* beneath the tip of the tongue.

In the Perameles, besides the minute and generally diffused simple papillæ, there are others of larger size, placed at distances of nearly a line apart, and raised about a third of a line above the surface of the dorsum. The fossulate or glandular papillæ correspond in number and arrangement with those of the Dasyures, but the entire tongue is relatively longer and more slender, especially in *Per. lagotis.*

In some species of Opossum, as *Didelphys Philander*, the margin of the tongue is fringed with a series of fine long papillæ.

In the Phalangers there is a thickening at the edge of the frænum linguæ, but no true lytta. The dorsal papillæ resemble those of the Dasyures, but are somewhat more obtuse.

In the Kangaroo there is a callous ridge along the middle of the under surface of the free extremity of the tongue, and a corresponding furrow along the dorsum; the latter is common to all the Marsupials. In the Wombat and Koala the dorsum of the tongue rises somewhat abruptly from a furrow surrounding its base; its form is narrow, moderately deep, diminishing in this respect to the tip, which is rounded. In both the Kangaroo and Koala there is a single large fossulate papilla near the base of the tongue.

The palate is sculptured in most Marsupials with transverse ridges. These are most numerous in the Bandicoots, being fourteen in the Perameles nasuta, and are slightly curved forwards. The roughness thus produced must aid the tongue in retaining small insects.

Digestive System.

Mouth.—The various modes of locomotion, resulting from the different modifications of the osseous and muscular systems observable in the several families of *Marsupialia*, relate to the acquisition of as various kinds of alimentary substances, which necessarily require for their assimilation as many adaptations of the digestive organs.

Food,—means of obtaining it,—instruments for preparing and mechanically dividing it,—cavities, canals and glands for chemically reducing and animalizing it,—form a closely connected chain of relationships and interdependencies. The usual sequence of anatomical description has here been followed in commencing with the consideration of the passive and active organs whose office it is to carry the stomach to the food and the food to the mouth, and we have now to describe the preparatory mechanical instruments in digestion, and the modifications and appendages of the alimentary canal.

The jaws of the Marsupialia are covered by well-developed fleshy lips; the upper lip is partially cleft in the Kangaroos, as in some of the Rodents; the muzzle is clad with hair in the Great Kangaroo and a few other species of *Macropus*, but in other Marsupialia it is naked and generally red from the vascularity of the integument.

The masticatory muscles of the jaws consist in the Marsupial, as in other Mammalia, of the temporal, the masseter, the external and internal pterygoids, and the digastricus. They are chiefly remarkable for the large proportional size of the masseter and internal pterygoid; the great developement of the latter muscle is constant in all the Marsupials, and is the condition of the peculiarly large and inflected angle of the lower jaw. The relative size of the masseter, as compared with the temporal muscle is greater in the herbivorous than in the carnivorous species, but this difference is much less in the Marsupial than in the corresponding placental genera. The extent of origin of the *temporal muscle* is indicated by the various conditions of the temporal and parietal crests; the inner surface of the zygomatic arch always affords origin to a portion of the fibres of this muscle, and in some species, as in the Koala, to all that portion of it which is inserted into the external fossa of the coronoid process and ascending ramus of the jaw, the fibres from the temporal and parietal bones being implanted on the inner side of the coronoid process. The *masseter* takes its origin by a strong band of tendinous and carneous fibres from the inferior and anterior part of the zygoma; the muscle expands as it is directed backwards, and is inserted into the ridge which bounds the external temporal fossa of the ascending ramus, and into the outer side of the inflected angle of the outer jaw. The *external pterygoid* takes its origin from the temporal plate of the sphenoid and the base of the pterygoid plate anterior to the sphenoidal bulla; the fibres converge to be implanted into the inner projecting side of the condyle of the jaw. The *internal pterygoid* arises from the outer depression of the longitudinally extended pterygoid plate already mentioned as characterizing the cranial structure of the Marsupials, and is implanted along the inner surface of the inflected angle of the jaw. The *digastricus* arises from the ex-occipital process; its fibres expand, and are inserted into the lower margin of the maxillary ramus, anterior to the commencement of the inflected angle of the jaw. The preceding description is taken from a dissection of the Koala. The masticatory muscles of the Wombat differ only in their relative proportions; the masseter in this gliriform Marsupial is single, presenting no trace of that subdivision and modified attachments which adapt it to the protraction of the lower jaw in the true Rodents, and accordingly the structure of the joint of the lower jaw of the Wombat exhibits, as already described, a corresponding difference from the Rodent type.

There is no toothless genus among the true Marsupials, unless the Monotremes which represent the Edentate order of the Placental Mammalia be regarded as modified Marsupials. Molar and incisor teeth are present in both jaws in every true Marsupial species; the canines are but feebly represented in many, as the Phalangers, Petaurists, &c. are wanting in the lower jaw in the Potoroos and Koala, and in both jaws in the Kangaroos and Wombat. The grinders, on the other hand, present their most complicated structure in these last cited herbivorous genera.

The Dasyures and Thylacine offer the carnivorous type of the dental system, but differ from the corresponding group of the Placental Mammalia in having the molars of a more uniform and simple structure, and the incisors in greater number; which number, however, is different in the different Marsupial carnivorous genera, as is expressed in the dental formulæ already given.

The canines are as formidable for their size, shape, and strength in the Thylacine and Ursine Dasyure, as in the Dog or Cat, and in a fossil species of the latter genus (*Dasyurus laniarius*),* which co-existed, in ancient Australia, with herbivorous Marsupials of greater size than now inhabit that continent, these teeth were as large as in the Leopard. In the Thylacine the points of the lower canines are received in hollows of the intermaxillary palatal plate when the mouth is closed, and do not project, as in the carnivorous placentals, beyond the margins of the intermaxillaries.

In some of the smaller species of the carnivorous group, as the *Phascogales*, the canines lose their great relative size, and the molar teeth present a surface more cuspidated than sectorial: there is also an increased number of teeth, and as a consequence of their more equable development they have fewer and shorter interspaces. Thus the *Phascogale penicillata* has, as Mr. Hunter observed, "a mouth full of teeth," and these are adapted for the capture and mastication of insects and other small and low organized animals.

In the Opossums the canines still exhibit a superior development in both jaws adapted for the destruction of living prey, but the molars have a conformation different from that which characterises the true flesh-feeders, and they consequently subsist on a mixed diet or lower organized animals; some, as the web-footed *Cheironectes*, betake themselves to the water, and prey, like the otter, on fish; others prowl about the sea-shore and subsist on crustacea, as the *Didelphys cancrivora*.

The *Perameles* are for the most part insectivorous; the incisors are always very small, the molars generally multicuspidate; some species, as *Per. nasuta*, have the canines not more developed than the premolars, which they closely resemble; but in others, as the *Per. lagotis*, they are proportionally as large as in the Opossums, and the inferior ones are concealed in the same position when the mouth is closed, as in the Thylacine. But the *Per. lagotis*, instead of exhibiting a corresponding approach in the structure of the molars to a carnivorous diet, have these unerring indicators of the nature of the food terminated by a broad oblique flattened surface, adapted to the trituration of farinaceous vegetable roots, the destruction of which is confidently attributed to this species of Bandicoot by the colonists of Swan River. The interesting genus *Myrmecobius* offers, in the small size and scattered distribution of its teeth, the nearest approach among the Marsupials to the edentate group of the Placental Mammalia; the multicuspidate structure of the molar teeth, and their small size, indicates that the Myrmecobius feeds chiefly on the weaker insects which are implied by its generic name. It is important to notice that in many of the Marsupials there is an inconstancy in the number of teeth in species of the same genus, and sometimes even in individuals in the same species; this at least appears to be the case in the *Myrmecobius*, in which, of three specimens examined, identical in all other respects, one had forty-eight, the other fifty-two, and the third fifty teeth. We have already pointed out the variety which obtains in the spurious and true molars of the Phalangers and Petaurists. The prominent feature in the change from the carnivorous to the herbivorous type of dentition is the inordinate development of the two middle incisors of the lower jaw, at the expense, as it would seem, of the posterior ones. In the *Phalangista Cookii*, e. g. six incisors are always present in the lower jaw, but only the first two have any functional character: the canine tooth again offers neither a form nor size by which it can be distinguished from the spurious molars; in the other Marsupials with the same characteristic modification of the hinder feet, including the Petaurists with the Phalangers, the small posterior incisors are wanting wholly or in part; the canines seem also to be lost, and the spurious molars are fewer, but variable in number. This inconstancy is not to be wondered at in teeth which have too simple a form and too insignificant a size to exercise any influence on the habits and economy of the species; and it would seem to be lost labour in the zoologist to attempt to found generic distinctions, and invent new names for the species in which these insignificant varieties are presented. The six incisors of the upper jaw and the two anterior ones in the lower jaw, with the true molars in both jaws, present a constancy of character and a functional importance in their development in all the *Phalangers* and *Petaurists*. These teeth

* See Major Mitchell's Australia, vol. ii.

are adapted, the first for cropping the foliage of the gum-trees (*Eucalypti*) and similar trees, and the others for bruising and masticating the same. The grinding surface of the molars generally presents four blunt tubercles.

The *Koala* resembles in its dentition and in its diet and arboreal life the Phalangers and Petaurists. In the lower jaw the absence of teeth between the two large procumbent incisors and the false molars is constant; in the upper jaw, however, the lateral or posterior incisors begin to exhibit the same diminution of size as the corresponding teeth in the lower jaw of some of the Phalangers, while the two anterior upper incisors present a proportional increase; the canines correspond in feebleness and form with the small incisors. In the Wombat, the defective development to which the teeth between the incisors and molars are subject in the Marsupial tribe, has reduced the dental formula of both jaws to the rodent type; but the shape, comparative shortness, and procumbent position of the two large inferior incisors, and the three-sided figure of the opposing pair above, bespeak the marsupial character of which this genus offers so extreme a modification. The grinders, however, agree with those of the herbivorous rodents in the absence of fangs, arising from the uninterrupted growth and ossification of their formative pulps; they offer also in both jaws an extreme degree of the curvature which characterises the molars of some herbivorous Rodents, as the Guinea-pig, and the great extinct gliriform Pachyderm, called Toxodon; but their chief distinctive peculiarity is the marsupial excess of number already mentioned.

With respect to the modifications of the teeth of the herbivorous Marsupials, it need only here be observed that the grinding surface of the true molars in the Kangaroos most resembles that which characterizes the same teeth in the Tapir, Dinothere, and Manatee.

No Marsupial possesses teeth composed of an intermixture of layers of dentine, enamel and cement throughout the crown, but the external layer of coronal cement is very conspicuous in transverse sections of the teeth of the Marsupials, viewed with the microscope, and forms a thick layer on the outside of the crowns of the teeth in the genera *Macropus*, *Phascolarctus*, and *Phascolomys*.

The modifications of the tongue and soft palate have already been noticed. In two species of Marsupials I have detected cheek-pouches. In the Koala they are wide and shallow, situated one on each side of the upper lip; the orifice is opposite the first superior premolar, and leads forwards above a horizontal fold of the mucous membrane which attaches the upper lip to the side of the intermaxillary bone, separating this part of the cheek-pouch from the mouth. In the *Perameles lagotis* there are also two small fossæ, one on the inside of each cheek, about four lines in diameter, and lined by a very distinct white epithelium.

The fauces are wide in the Zoophagous, but narrow in the Entomophagous and Phytophagous Marsupials.

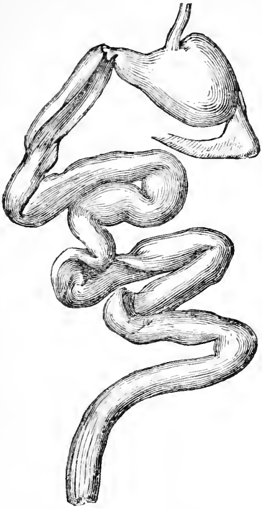
Alimentary canal.—The *œsophagus* in passing through the chest recedes from the spine as it approaches the diaphragm, and is loosely connected with the bodies of the dorsal vertebræ by a broad duplicature of the serous membrane of the posterior mediastinum. In the Phalangers the œsophagus terminates in the stomach almost as soon as it has pierced the diaphragm; in the Opossums it is continued some way into the abdomen; in the *Didelphys Virginiana*, for example, for the extent of an inch and a half; in *Did. brachyura*, for half an inch. In the Kangaroos the abdominal portion of the œsophagus is of still greater extent; I have observed it five inches long in a male *Macropus major*.

The inner surface of the œsophagus is generally smooth, or disposed in fine longitudinal plaits; but in the Virginian Opossum the terminal part of the œsophagus presents many transverse folds of the lining membrane analogous to, but relatively larger than those in the Lion and other *Felines*. I have not met with a like structure in the Phalangers nor in any other genus of Marsupials; what is more remarkable is that the transverse œsophageal rugæ are not developed in the carnivorous *Dasyures* or *Phascogales*, where analogy would lead one to expect them, rather than in the insectivorous Opossums.

The *stomach* presents three leading modifications of structure in the Marsupialia; it is either simple, as in the Zoophagous, Entomophagous, and Carpophagous tribes; or is provided with a cardiac glandular apparatus, as in the Koala and Wombat; or is complicated by sacculi, as in the Poephagans.

It might have been expected that the stomach would have exhibited some modifications in the development of the left or cardiac extremity corresponding with the differences of food and dentition observable in the large proportion of the Marsupial order, in which this viscus presents its simple condition; but this is not the case: the form of the stomach is essentially the same in the carnivorous Dasyure, the insectivorous Bandicoot, and the leaf-eating Phalangers. It presents a full, round, ovate, or sub-triangular figure, with the right extremity projecting beyond and below the pylorus; the longitudinal diameter seldom exceeds the vertical or transverse by more than one-third; often, as in *Phascogale* and *Dasyurus viverrinus*, by only one-fourth of its own extent; and the œsophagus enters at the middle of the lesser curvature, or sometimes nearer the pylorus, but always leaves a large hemispherical cul-de-sac on the left side. Daubenton has given illustrations of this characteristic form of the stomach in different species of *Didelphys;* it is here figured as it exists in the *Phascogale* (*fig.* 122). The stomach is relatively much more capacious in the carnivorous Marsupials than in the carnivorous Placentals. Some slight modifications occur in the disposition of the lining membrane; thus in the *Phascogale* I observed a series of very thick rugæ radiating from the middle of the upper part of the cœcal end of the stomach, some of which were continued along the lesser curvature to the pylorus. Dr. Grant found, in the *Perameles nasuta*, that " the

Fig. 122.

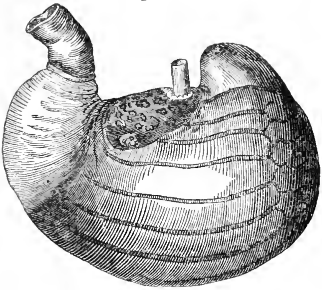


Alimentary canal, Phascogale flavipes.

internal surface of the left cul-de-sac was quite smooth and villous (?), while the right half of the stomach was entirely covered internally with rugæ, running chiefly in a longitudinal direction, and particularly numerous towards the pylorus."*

The stomach in the Wombat and Koala does not materially differ in external figure from that of the above-cited Marsupials; the œsophagus terminates nearly midway between the right and left extremities, but further from the pylorus in the Wombat than in the Koala. The conglomerate gastric gland is of a flattened ovate form, relatively larger in the Wombat than in the Koala, situated to the left of the cardiac orifice, at the lesser curvature of the stomach (*fig.* 123). The gastric gland has a similar position in the

Fig. 123.



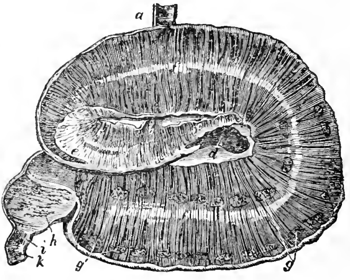
Stomach of the Wombat, inverted.

* Wernerian Transactions, vol. vi. p. 199.

Beaver, but in this animal the excretory orifices of the gland are arranged in three longitudinal rows, while in the Wombat and Koala they are scattered irregularly; in the Wombat they are about thirty in number, and the bottoms of the larger depressions are subdivided into smaller cells. In the partially contracted state the inner membrane of the stomach of the Wombat, as represented in the figure, is disposed in pretty regular longitudinal rugæ, which gradually subside towards the pylorus; but when the stomach is distended these folds disappear, and the left extremity presents a full globular form. In the Wombat dissected by me the œsophagus terminated nearer the pylorus than is represented in the figure here given from the Comparative Anatomy of Sir Everard Home.

The sacculated stomach of the Kangaroo, which offers the extreme modification of this organ in the Marsupial order, resembles the human colon both in its longitudinal extent, structure, and disposition in the abdomen. The natural relative position of this singular viscus is, however, very different from that described by Sir Everard Home,* who evidently has taken his account from the drawing by Mr. Clift, from which our *fig.* 124 is taken: the object of this drawing, however, being to pourtray the modifications of the inner surface of the Kangaroo's stomach, it is artificially disposed accordingly. In a full-grown female Kangaroo (*Macropus major*), I found the abdominal œsophagus four inches long, and terminating at six inches distance from the left extremity of the stomach: this extremity was folded forwards and to the right in front of the œsophagus; from the basis of the left cul-de-sac the stomach continued to expand, and descended into the left lumbar and iliac regions, whence it stretched upwards and to the right side obliquely across the abdomen, to the right hypochondrium, where it became contracted

Fig. 124.



Stomach of the Kangaroo.

and finally bent downwards and backwards to terminate in the duodenum. The whole length of the stomach, following its curvatures, was three feet six inches, equalling that of the animal itself from the muzzle to the vent.

* Lectures on Comp. Anatomy, i. p. 156.

The stomach of the Kangaroo may be regarded as consisting of a left, a middle, and a right or pyloric division. The left extremity of the stomach is bifid, and terminates in two round cul-de-sacs. The sacculi of the stomach are produced, like those of the colon, by three narrow longitudinal bands of muscular fibres, which gradually disappear, together with the sacculi at the pyloric division. One of the longitudinal bands runs along the greater curvature, at the line of attachment of the gastro-colic omentum; the others commence at the base of the left terminal pouches, and run, one along the anterior, the other along the posterior side of the stomach: the interspace, between these bands, forming the lesser curvature of the stomach, is not sacculated. The largest of the two terminal sacculi (*d*, *fig.* 124) is lined with an insulated patch of vascular mucous membrane, which is continued for the extent of five inches into the cardiac cavity; the epithelium is continued from the œsophagus in one direction into the nearest and smallest sacculus, and extends in a sharp-pointed form for a considerable distance in the opposite direction into a series of sacculi in the middle compartment of the stomach (*c*): this epithelium is quite smooth. The vascular mucous surface recommences by a point at the great curvature, near the beginning of the middle compartment, and gradually expands until it forms the lining of the whole inner surface of the right half of the stomach. Three rows of clusters of mucous follicles (*g*, *g*) are developed in the mucous membrane of the pyloric half of the middle compartment; they are placed parallel with the longitudinal muscular bands: about fifteen patches are situated along the greater curvature, and there are nine in each of the anterior and posterior rows. These glandular patches disappear altogether in the pyloric compartment of the stomach, where the lining membrane is thickened, and finely corrugated; but immediately beyond the pylorus there is a circular mucous gland three-fourths of an inch broad: the non-sacculated pyloric division of the stomach was five inches in length.

In the smaller species of Kangaroo the stomach is less complicated than in the *Macropus major;* the number of sacculi is fewer: in *Macropus Parryi*, Ben. the third longitudinal band at the great curvature of the stomach is almost obsolete: in the Brush-tailed or Rock Kangaroo, (*Macropus penicillatus,*) the cardiac extremity terminates in a single sub-clavate cul-de-sac. In all the species which I have examined the œsophagus terminates in the middle division of the stomach, close to the produced crescentic fold which separates it from the cardiac compartment. In the great Kangaroo a second slighter fold is continued from the right side of the cardiac orifice parallel with the preceding, and forming with it a canal, somewhat analogous to that in the true ruminating stomachs, and along which fluids, or solid food not requiring previous preparation in the cardiac cavity, might be conducted into the middle compartment.

I have more than once observed the act of rumination in the Kangaroos kept in the Vivarium of the Zoological Society. It does not take place while they are recumbent, but when the animal is erect upon the tripod of the hind legs and tail. The abdominal muscles are in violent action for a few seconds, the head is then a little depressed, and the cud is masticated by a rapid rotatory motion of the jaws. This act is by no means repeated in the Kangaroos with the same frequency or regularity as in the true Ruminants. A fact may, however, be noticed as an additional analogy between them; balls of hair, cemented by mucus, adpressed and arranged in the same direction, are occasionally formed in the stomach, of which I have met with two, of an oval shape, in the *Macropus Parryi*.

In the genus *Hypsiprymnus* the stomach is as singularly complicated as in the Kangaroos, and the complication is essentially the same in both; arising from the sacculation of the parietes of a very long canal by a partial disposition of shorter bands of longitudinal fibres; but in the Potoroos this sacculation is confined to that part of the stomach which lies to the left of the œsophagus, while the right division of the cavity has the ordinary form and structure of the pyloric moiety of a simple stomach. The left or cardiac division is enormously developed; in relative proportion, indeed, it is surpassed only by the true ruminant stomachs, in which both the rumen and reticulum are expansions of the corresponding or cardiac moiety of the stomach. The relation of the stomach of a Potoroo to that of a Kangaroo may be concisely expressed by stating that the termination of the œsophagus in the former is removed from the commencement of the middle sacculated compartment to its termination.

When fluid is injected into the stomach of a dead Potoroo, it distends first the pyloric division; it is probably by a kind of antiperistaltic action that the aliment is propelled into the long sacculated cœcum to the left of the œsophagus.

The modifications of the *epiploon*, as an appendage to the stomach, may here be noticed. In the Kangaroo it is of very moderate size, being continued loosely from the stomach to the transverse colon, but not extended beyond that part. The posterior layer lies between the stomach and the intestines, and affords a good illustration of one of the uses of the epiploon, as it evidently prevents these parts from interfering with each other's motions. The anterior layer generally contains more or less fat. In the Petaurus the great omentum is continued from the great curvature of the stomach, and the commencement of the duodenum. In the Phalangers it is of considerable extent, and is usually loaded with fat. In the Opossums I have found it generally devoid of fat, when this substance has been accumulated in other parts. In the Phascogales and Dasyures the epiploon is of moderate size, and contains little or no fat.

Having seen that, with the exception of the Potoroos and Kangaroos, the stomach is simple in the *Marsupialia*, presenting only some additional mucous glands in the Koala and Wombat, it is to the succeeding parts of the alimentary canal that we have to look for those modifications which should correspond with a vegetable, a mixed, or an animal diet; and never perhaps was a physiological problem more clearly illustrated by comparative anatomy than is the use of the cœcum coli by the varying conditions which it presents in the present group of Mammalia.

In the most purely carnivorous group of the Marsupial order the stomach presents in the magnitude of the left cul-de-sac a structure better adapted for the retention of food than we find in the stomachs of the corresponding group in the placental series. In the most strictly carnivorous *Feræ*, as the cat-tribe, there is a cœcum, though it is simple and short; but in the Marsupial Zoophaga this part is entirely wanting, and the intestinal canal, short and wide,* is continued, like the intestine of a reptile, along the margin of a single and simple mesentery from the pylorus to the rectum.

In the Entomophagous Marsupials, some of which are suspected with reason to have a mixed diet, the intestinal canal is relatively longer; the distinction of small and large intestine is established; and the latter division commences with a simple, moderate-sized, subclavate cœcum.

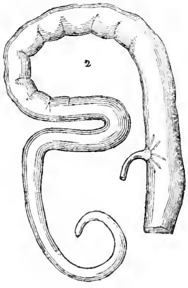
Fig. 125.

Cœcum of an Opossum.

In the Carpophagous Phalangers, whose stomach resembles that of the predatory Dasyure, the compensation is made by a longer intestine, but principally by the extraordinary length of the cœcum, which ir some species is twice that of the body itself.

Lastly, in the Koala, which is, perhaps, a more strictly vegetable feeder than the Petaurists or Phalangers, the cœcum is more than three times the length of the animal, and its essential part, the inner secreting membrane is farther augmented by about a dozen longitudinal parallel, or nearly parallel, plaits, which are continued from the colon three-fourths of the way towards the blind extremity. When we reflect that the Sloth, which has the same diet and corresponding habits with the Koala, has a singularly complicated stomach, but no cœcum, the vicarious office of this lower blind production of the digestive tube as a subsidiary stomach is still more strikingly exemplified. What then, it may be asked, is the condition of the cœcum in the Marsupials with enormous sacculated stomachs? It is in these species comparatively short and simple. In the Potoroos which scratch up the soil in search of farinaceous roots, it is much shorter than in the great Kangaroos which browze on grass. There is a slight tendency to sacculation at the commencement of the cœcum in the latter Marsupials, by the development of two longitudinal bands (*fig.* 127).

Fig. 126.



Cœcum of the Koala.

* The jejunum, in the Thylacine, has a diameter of two inches and a half.

Fig. 127.

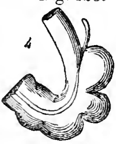
Cœcum of the Kangaroo.

In the Wombat the cœcum is extremely short, but wide; it is remarkable for being provided with a vermiform appendage.

In this animal, however, the colon is relatively longer, larger, and it is puckered up into sacculi by two broad longitudinal bands. In the specimen dissected by me, one of these sacculi was so much longer than the rest as to almost merit special notice as a second cœcum.

The most interesting peculiarity which the Zoophagous Marsupials exhibit in the disposition of their simple intestinal canal, consists in its being suspended from the very commencement of the duodenum on a simple and continuous mesentery, like the intestine of a carnivorous reptile. The duodenum makes the ordinary fold on the right side, but it is not tied to the spine at its termination; the commencement of the jejunum may, however, be distinguished by a slight twist of the mesentery, and a fold of peritoneum is continued from the lowest curve of the loop of the duodenum to the right iliac region, as in the Kangaroos. The intestine is a little narrower at its middle part than at its two extremes; the tunics increase in thickness towards the rectum. There is a zone of glands at the commencement of the duodenum.

Fig. 128.



Cœcum of the Wombat.

In the *Entomophaga* the duodenum is tightly connected to the spine, where it crosses to be continued into the *jejunum*: from this part the mesentery is continued uninterruptedly along the small intestines and colon to the rectum; so that although the cœcum is generally found on the right side, its connections are sufficiently loose to admit of a change of position.

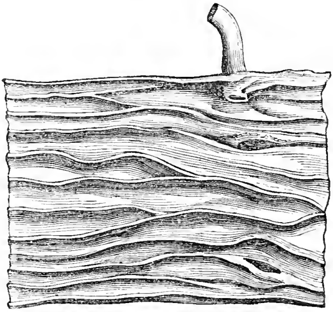
In the *Petaurus pygmæus* the duodenum is attached to the spine as in the Opossums, but it is not tied down to the right iliac region by a fold of peritoneum continued from the convexity of its depending curve. I found the cœcum in this species disposed in a spiral curve in the left lumbar region; the colon ascended a little way in front of the stomach, receiving a branch of the superior mesenteric artery, and was then continued straight down to the anus; thus we are again reminded of the oviparous character by the shortness of the large intestine.

In the *Pet. taguanoides* the duodenum is tied down to the iliac region, as in the Dasyure; the cœcum is four inches long, and the colon is relatively longer than in the *Acrobates;* it makes the tour of the abdomen much as in man, but is continued into the rectum without forming a sigmoid flexure.

In the Phalangers the duodenum winds round the root of the mesentery, descending pretty low down on the right side, and becoming a loose intestine or jejunum on the left side. The long cœcum is suspended by a broad duplicature of peritoneum continued from the mesocolon; and the colon is closely attached at its transverse arch to the duodenum and root of the mesentery.

In the Koala the cœcum and large intestines arrive at their maximum of development. The duodenum commences with a small pyriform sacculus nearly an inch in breadth, and soon contracts to a diameter of five lines, which is the general calibre of the small intestines. The large intestines, where the ilium terminates, have a diameter of two inches. The end of the ileum (*a, fig.* 129) protrudes for the extent

Fig. 129.



Ileo-cœcal valve, Koala. Half its natural size.

of a quarter of an inch within the cœcum, forming a very effectual valve: near this part there are two wide and deep glandular fossæ: the longitudinal valvulæ conniventes of the large intestines have already been noticed.

In the Potoroos the small intestines are disposed nearly as in the Phalangers: the short and wide cœcum lies in the right hypogastrium: the colon makes the usual tour of the abdomen, but is disposed in long convolutions through its whole course, being suspended on a broad mesocolon. The diameter of both small and large intestines is nearly the same: in *Hyps. setosus* I found this to be half-an-inch.

In the great Kangaroo the descending portion of the duodenum is attached posteriorly, by means of a thin peritoneal duplicature, to the spine, and anteriorly to the ascending colon: it makes an abrupt turn upon itself, and a fold of peritoneum is continued from the convexity of the curve to the right iliac region. The small intestines are strung in short folds on a rather narrow mesentery. The cœcum is in part suspended from the same mesenteric fold. The colon, besides its posterior connexions with a mesocolon, is attached, as before observed, to the duodenum; and also, by means of the great omentum, pretty closely to the stomach, whence it passes down, forming many large and loose convolutions to the rectum, being attached by a broad mesocolon to the left hypochondriac region.

The zone of glands at the commencement of the duodenum has been already noticed; they are present in other Marsupials, even in the most carnivorous species; but I have not met with a similar structure in the placental Mammalia. The villi of the small intestines in the Kangaroo are of moderate length, compressed and close-set. Glandulæ aggregatæ are arranged in narrow patches in the ileum. There are seven groups of similar follicles in the cœcum; and a few long and narrow patches of glands occur in the colon intermingled with numerous glandulæ solitariæ; the surface of the rest of the lining membrane of the large intestine is disposed in a very fine net-work.

Two faint longitudinal bands extend along the first ten inches of the colon and are continued along two-thirds of the cœcum: the sacculi produced by these bands are but very feebly marked. I have not met with any example in the *Macropus major* of a cœcum, which, either naturally or when inflated and dried, presented the sacculated structure represented by Cuvier in *fig.* 8, *pl.* xxxix. of the Leçons d'Anat. Comparée.

The contents of the cœcum in the great Kangaroo are of a pultaceous consistence, and the mass continues undivided along the first two feet of the colon, gradually becoming less fluid and then beginning to be separated into cubical fæces about an inch square. The diameter of the large intestine in this species exceeds very little that of the small intestines.

In all the Marsupials two sebaceous follicles open into the termination of the rectum. The anus has its proper sphincter, but is also surrounded, in common with the genital outlet, by a larger one. When the penis is retracted, the fæcal, urinary, and genital canals all terminate within a common external outlet; so that in the literal sense the Marsupials are monotrematous.

The following is a table of the length of the intestinal canal, and its parts in a few species of the different families of Marsupialia.

Table of the length of the intestinal canal as compared with the body.

Salivary glands.—These glands in the Carnivorous Dasyures consist of a small parotid and a large submaxillary gland on each side. I searched expressly, but in vain, for the zygomatic gland; the Dasyures do not agree with the dogs in having these glands. They have no sublingual gland. The submaxillary gland is placed in front of the neck, so that its duct passes on the dermal side of the tendon of the biventer maxillæ, and terminates half an inch from the symphysis menti. There is a thick row of labial glands along the lower lip. The Opossums and Bandicoots present a similar salivary system.

In the *Phalangista vulpina* there is a sublingual gland on each side of a firm texture, about one inch in length and three lines broad; a roundish submaxillary gland about the size of a hazel-nut; and a broad and flat parotid, larger than in the Entomophagous or Sarcophagous Marsupials.

The parotid glands are relatively larger in the Koala, in which the duct takes the usual course over the masseter and enters the mouth opposite the third true molar, counting backwards.

In the Wombat I found the parotid glands very thin, situated upon both the outer and inner side of the broad posterior portion of the lower jaw; the duct passed directly upwards and outwards to the insertion of the sterno-cleido-mastoideus; here it was buried in the cellular substance anterior to that muscle, then turned over the ramus of the jaw, and, pursuing a somewhat tortuous course over the masseter, entered the mouth just anterior to the edge of the buccinator. The submaxillary glands were each about the size of a walnut; their ducts terminated as usual on each side of the frænum linguæ.

In the great Kangaroo the parotid is very large, extending from below the auditory meatus three or four inches down the neck. In the *Hypsiprymnus* it reaches as far as the clavicle. In both cases this gland is separated from the submaxillary gland by the submaxillary vein.

The *tonsils* are small in all the Marsupials, but are not represented in the carnivorous species, as in the Placental Feræ, by simple glandular pouches at the sides of the fauces; for example, they consist of an oblong glandular body on each side in the *Dasyurus macrurus*.

The liver.—The liver is subdivided into many lobes in all the Marsupial genera. It is relatively largest in the burrowing Wombat and carnivorous Dasyure; relatively smallest in the graminivorous Kangaroo, in which it is situated, as in the placental Ruminants, entirely to the right of the mesial plane. The small or Spigelian lobe, which fits into the lesser curve of the stomach, is given off from the left lobe of the liver in the Kangaroos, but from the right in most other Marsupials; the difference just noticed in the Kangaroo depends on the peculiar disposition of its remarkable stomach.

In the Koala the under surface of the liver (*fig.* 130) is singularly sculptured and subdivided into thirty or forty lobules; this condition is presented in a minor degree in the liver of the Ursine Dasyure.

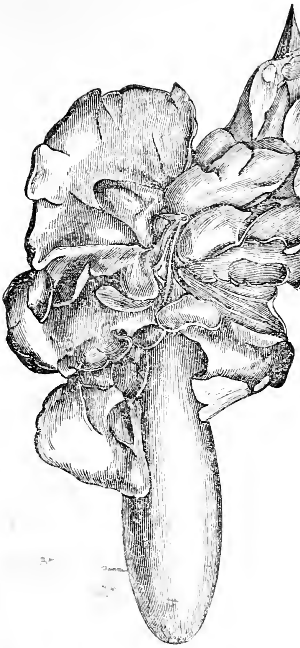
In a long-tailed Dasyure, which weighed 3 lbs. $8\frac{1}{4}$ oz., the liver weighed $3\frac{1}{2}$ oz. avoirdupoise.

The gall-bladder is present in all the Marsupials, and is generally of large size and loosely lodged in a deep cleft of the cystic lobe. In the Opossum it generally perforates that lobe, and the fundus appears at a round opening on

* These admeasurements were obligingly communicated to me by my friend Mr. Hobson, of Hobart Town, Van Dieman's Land, and were taken from an animal killed in the wild state. I subjoin the admeasurements of an individual of the same species which died after a year's confinement in the Zoological Gardens: there is a considerable difference in the length of the intestinal canal and especially of the cœcum; and it may be allowable to speculate upon the influence which difference of diet and confinement may have had in producing this difference. Mr. Martin's admeasurements of another *Phal. Vulpina* agree more nearly with mine. —See Zool. Proceedings, 1837.

† The vermiform process measures two inches in length.

Fig. 130.



Liver of the Koala.

the convex surface of the liver. The coats of the ductus choledochus are thickened towards its termination, and become the seat of numerous mucous cysts which open into the interior of the duct.

In the Phalangers the terminal half-inch of the ductus choledochus is similarly enlarged and glandular. The biliary and pancreatic ducts generally unite together before perforating the duodenum. In the Virginian Opossum, the long-nosed Bandicoot, and the long-tailed Dasyure they pour their secretions into the gut an inch from the pylorus. In the great Kangaroo the glandular ductus choledochus is joined by the pancreatic duct, and terminates in the duodenum five inches from the pylorus.

The pancreas.—The pancreas extends as usual from the duodenum to the spleen, behind the stomach; it is characterized by a process sent off at right angles, or nearly so, to the main lobe at or near its left extremity. I have observed other small and thin processes branching out into the duodenal mesentery in a Phalanger; and similar but still more numerous processes, so as to give the organ a dendritic appearance in the Kangaroo; but the first-named process is constant.

The spleen.—It is interesting to observe that the spleen corresponds in this triangular or T-shaped figure with the pancreas. In the great Kangaroo (*Macropus major*) I found the main body of the spleen ten inches long, and the rectangular process six inches; both parts were narrow and thin.

Absorbents.—The lacteal absorbents form, in the *Dasyurus viverrinus*, two thin, subelongate, dark-coloured mesenteric glands: one of these is situated near the pylorus, at the end of the pancreas. The plexiform cysterna chyli is situated in the Kangaroo (*Macropus Parryi* was the species from which the following description is taken) upon the crura of the diaphragm, and extends upon the right side above the diaphragm into the thorax. Two thoracic ducts are continued from the cysterna, one along the left, the other along the right side of the bodies of the dorsal vertebræ. The right duct crosses the seventh vertebra and joins the left, which again divides and reunites, forming a slight plexus, before finally terminating at the confluence of the left subclavian and jugular veins. The double thoracic duct in the Kangaroo was first noticed by Dr. Hodgkin; it is interesting, on account of its resemblance to the characteristic condition of the great nutrient conduit in the Bird and Crocodile; in these, however, each division terminates in the vena innominata of its own side, which was not the case in the Kangaroo above described.

Blood.—From the characteristic elliptical form of the blood-discs of Birds and Reptiles, and the rare occurrence of that form, as in the exceptional case of the Camel tribe, among the placental Mammalia, the examination of these particles of the circulating fluid in the Marsupial genera was attended with more than ordinary interest, and the results, derived from a comparison of species belonging to all the leading groups, show that the different tribes of Marsupial animals correspond with the analogous placental Mammalia both in the circular or subcircular contour of the blood-discs, and very nearly also in their size.*

Dasyurus viverrinus.—The blood-discs of this small carnivorous Marsupial were sensibly larger than those of the analogous placental Mammalia, as the Cat. The ordinary or unbroken discs had their margin rounded off. The number of the granulated discs was considerable; many of them presented a well-defined margin, notched like a cog-wheel. The average diameter obtained by me was $\frac{1}{4200}$th of an inch.

Dasyurus ursinus.—The average diameter of the blood-discs is $\frac{1}{3800}$: observed extremes of size $\frac{1}{2800}$ and $\frac{1}{4520}$.

Perameles lagotis.—The blood of this Marsupial, which was examined while recently drawn from the living animal, and under the same circumstances as that of the two species of *Dasyure*, presented a still greater number of the granulated blood-discs mixed with others of the ordinary form. The descriptions of such altered blood-discs not only by Hewson and Falconer, and in recent times by Professor

* See Medical Gazette, November 13, 1839, and Mr. Gulliver's observations, London and Edinb. Philos. Magazine, February, 1840.

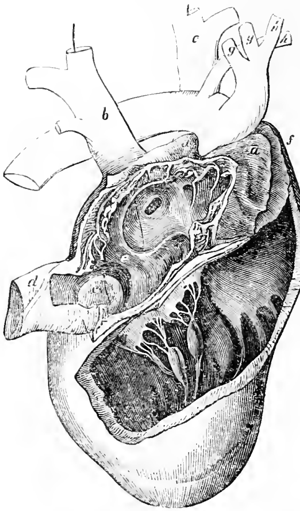
Wagner, (Hecker's Literärische Annalen, Februarheft, 1834,) but also in works in our own language, as in Hodgkin's Translation of Edwards's Influence of Physical Agents on Life, Appendix, p. 438, 1832, have rendered the fact sufficiently familiar. But the connection of this well-known appearance with the mode of formation or multiplication of the blood particles had not before attracted the attention it seemed to deserve; on this subject I have elsewhere remarked: "In some of the granulated blood-discs of the Perameles the subdivisions producing that appearance were fewer and larger, and were separated by deeper clefts than I had before observed; they suggested to me the idea that the blood-disc was undergoing a spontaneous subdivision into smaller vesicles, and, although my observations are not at present sufficiently numerous to warrant the hypothesis that the development of smaller vesicles within itself is a normal property of the ordinary coloured vesicle or blood-disc, yet the obscurity which still hangs over the origin and reproduction of the blood-discs, and the unexpected constancy of the granulated form in a greater or less proportion of them while recent, and floating in the serum, in different species of animals examined by me, makes me unwilling to suppress any idea naturally arising out of such observations and likely to be suggestive of examination of the same appearances by other microscopical observers."* The general form of the blood-vesicles of the Perameles is the usual circular flattened disc: they presented a greater variety of size than in the *Daysurus*, but upon the whole a larger average diameter, viz. $\frac{1}{3948}$th of an English inch.

Phalangista Vulpina.—Average diameter of blood-disc $\frac{1}{3700}$th inch.
Petaurus sciureus.—Ditto ditto $\frac{1}{3800}$th inch.
Macropus penicillatus.—Do. do. $\frac{1}{4200}$th inch.
Macropus major.—Ditto ditto $\frac{1}{4000}$th inch.
Phascolomys Vombatus.—Do. do. $\frac{1}{3600}$th inch.

The results of the present observations on the blood of the Marsupial quadrupeds correspond generally with those obtained from the placental Mammalia, inasmuch as the blood-discs of the species which derives its nutriment from the greatest variety of organized substances, as the Perameles, which subsists on insects, worms, and the farinaceous and succulent vegetables, are larger than those of the strictly carnivorous Dasyure, and of the herbivorous Kangaroo, the blood-discs of the latter, like those of the placental Ruminant, being the smallest, though not in the same proportion. In each natural group of Marsupialia there is a direct relation between the size of the blood-disc and that of the species.

Heart.—The heart is inclosed in a pericardium, and situated in the same relation to the lungs, mediastinum, and thoracic cavity as in the Rodent and most other mammiferous quadrupeds. It offers no peculiarity in its general outward form. The apex is less obtuse in some species, as the Phalanger and Wombat, than in others, as the Kangaroo. The serous layer of the pericardium is reflected upon the large vessels near to the heart. The fibrous layer of the pericardium adheres to the sternum in the Kangaroo. The appendix of the right auricle is always divided into two angular processes, (*a*, *a*, *figs.* 131 and 132,) one in front and the other behind the trunk of the aorta.

Fig. 131.



Heart of the Kangaroo.

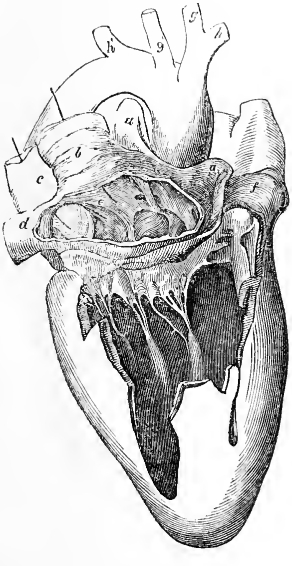
Besides this characteristic modification of its external form, the right auricle presents some still more essentially marsupial conditions in its interior. There is no trace, for example, of a 'fossa ovalis' or an 'annulus ovalis' in any marsupial animal;* and the absence of these structures, which are present in the heart of all the placental Mammalia, doubtless relates to the very brief period during which the auricles intercommunicate in the Marsupials, and to the minute size, and in other respects incompletely developed state, at which the young marsupial animal respires air by the lungs, and has the mature condition of the pulmonary circulation established. The right and left auricles intercommunicate by an oblique fissure in the uterine embryo of the Kangaroo, when two-thirds of the period of gestation is past, but every trace of this fœtal structure is obliterated in the subsequent growth of the heart; so that in the mature animal the wide terminal orifice of the posterior cava is

* Medical Gazette, 1839, l. c. My hypothesis has received a certain degree of confirmation by the subsequently published observations on the division of the corpuscles of the blood by Mr. Quekett, (Med. Gazette, January, 1840,) and by Dr. Martin Barry, Philos. Trans. 1840, p. 595.

* Physiological Catalogue, Mus. Royal College of Surgeons, 4to. vol. ii. p. 52.

separated from that of the anterior cava by a simple crescentic ridge (*e*, *figs.* 131 and 132), which forms a salient angle of the parietes of the auricle between these apertures. The anterior cava (*b*) returns the blood from the right side of the head and the right anterior extremity; the corresponding vein on the left side (*c*) passes down in all the Marsupials, as in Birds and Reptiles, behind the left auricle, below the two pulmonary veins, and, after receiving the coronary vein, joins the inferior cava (*d*) immediately before its expansion into the auricle.

Fig. 132.



Heart of the Wombat.

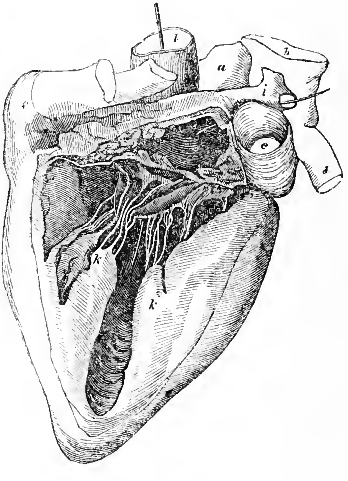
Where the posterior extremities are less or not larger than the anterior ones, as in the Ursine Dasyure and Wombat, the posterior cava is somewhat less than the left vena innominata (*figs.* 131 and 132), and they appear to terminate by separate apertures in the auricle; but in the Kangaroo (*fig.* 131) the proportions of the two veins are reversed, and the posterior cava more obviously receives the left vena innominata before it terminates: these two veins meet at a very acute angle, and are separated by a crescentic ridge similar to, but thinner than, that which divides their common orifice from the orifice of the anterior cava.

The right auriculo-ventricular valve is membranous, as in the placental Mammalia, and its free margin is attached by fine chordæ tendineæ to three columnæ carneæ; these in the Kangaroo (*fig.* 131) all arise from the septum of the ventricles, but in the Wombat (*fig.* 132) the base of two of the columnæ is situated at the angle between the septum and the thin outer wall of the ventricle.

The right ventricle extends nearly to the apex of the heart in the Wombat, but falls short of that part in the Kangaroo. The ventricle is continued in the form of a pyramidal process, somewhat resembling a *bulbus arteriosus*, to the origin of the pulmonary artery (*f*, *figs.* 131 and 132), and projects beyond the general surface of the heart further than in ordinary Mammalia.

The appendix of the left auricle is notched in the Kangaroo to receive the apex of this process, but not in the Wombat. Two pulmonary veins (*i*, *fig.* 133) terminate close together, or by a single trunk, at the upper and dextral angle of this auricle. The mitral valve is regulated by two short and thick columnæ (*k*, *k*, *fig.* 133), which send their tendinous chords to the margin and ventricular surface of the valve.

Fig. 133.



Heart of the Wombat.

The ventricles and auricles present the usual mammalian proportions and relative thickness of their parietes. Three sigmoid valves are situated at the origin of the pulmonary artery, and the same number at that of the aorta.

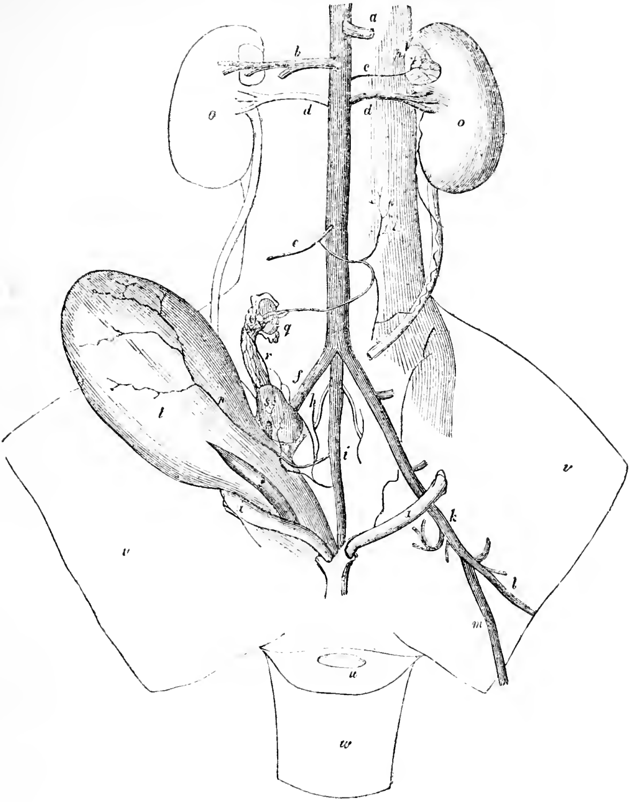
After the coronary arteries, the primary branches from the arch of the aorta rise in some species by three, in others by two trunks. The broad-chested Marsupials, the Koala and Wombat for instance, are those in which the left carotid (*g*′, *fig.* 132) and subclavian (*h*′) arise separately from the arch; the arteria innominata dividing into the right subclavian and carotid (*g*, *h*, *fig.* 132), as in man. In most of the other Marsupials the innominata gives off both carotids (*g*, *g*, *fig.* 131) as well as the right subclavian (*h*); and the left subclavian (*h*) alone has a separate origin. The common carotid in the Kangaroo gives off the thyroid artery, and afterwards divides opposite the transverse process of the atlas into the external and internal carotids. The internal carotid describes a sharp curve at its origin, and passes along the groove between the occipital condyle and the exoccipital process to the foramen caroticum. The vertebral arteries are given off by the subclavians, and pass to the skull, as usual, through the vertebral foramina of the cervical transverse processes. They unite beneath the medulla oblongata to form the basilar artery, which sends off at right angles to the cerebellum two branches as large as itself: it divides opposite the anterior margin of the pons Varolii, and the diverging branches are connected by two straight transverse canals, before they anastomose with the internal carotids to form the circle of Willis. No peculiarly marsupial condition occurs in the distribution of the other arteries of the head, or those of the neck, the chest, and anterior extremities; but I may observe that in the Koala, Wombat, Kangaroos, Potoroos, most Phalangers, (*Phal. Cookii* is an exception,) most Petaurists, (*Pet. Sciureus* is an exception,) the Opossums, Bandicoots, and Phascogales, the brachial artery perforates the internal condyle of the humerus; it passes over that condyle, impressing it with a more or less deep groove in the Dasyures and Thylacine.

In the abdomen, the primary branches of the aorta are sent off in the same order as in most of the ordinary Mammalia, with the exception of the constant absence of an inferior mesenteric artery. This modification probably relates to the simplicity of the mesenteric attachment of the intestines above described. A still more marked example of the oviparous affinities of the Marsupialia, as exemplified in the arterial system, occurs in the mode of origin of the great arteries of the posterior extremities. In Man and the ordinary Mammalia these are derived, as is well known, from a single trunk on each side—the common iliac artery; in Birds from two primary branches of the aorta, one corresponding with the external iliac and femoral, the other with the internal iliac and ischiadic arteries. In the Kangaroo and Phalangista vulpina the aorta gives off, opposite the interspace of the two last lumbar vertebræ, the iliac arteries; but these are afterwards resolved into the ordinary branches of the external iliac of the placental Mammalia, with the addition of the ilio-lumbar artery. The trunk of the aorta, much diminished in size, maintains its usual course for a very short distance, and then gives off the two internal iliacs, and is continued as the 'arteria sacra media' to the tail. The transitional character of this part of the marsupial sanguiferous system between the oviparous and placental types, is manifested in the large size of the external iliacs as compared with the internal iliacs, their greater share in the supply of blood to the hinder extremities, and the brevity of the aortic trunk between their origins. In most Birds the femorals or external iliacs are smaller than the ischiadic or internal iliac arteries subsequently given off. At the upper part of the thigh the femoral artery divides into two equal branches; the one which corresponds with the radial artery in the fore leg (*m*, *fig.* 134) principally supplies the foot in the Kangaroos; it passes along the back of the radius, between the gastrocnemius internus and tibialis posticus, and divides a little above the internal malleolus. The smaller division (*l*, *fig.* 134), which follows the ordinary course of the femoral along the popliteal space, is lost upon the inner and posterior part of the tarsus; the larger branch winds over the malleolus to the front of the tarsus, sends off the anterior tarsal artery, and is then continued along the inner and afterwards the under part of the metatarsal bone of the long and strong toe.

In *fig.* 134, *a* is the trunk of the cœliac artery; *b* that of the superior and inferior mesenteric arteries; *c* is the capsular artery of the left side; *d*, *d*, the renal arteries; *e* the spermatic artery, of which the left branch is shown continued to the left ovarium *q*, which, with the uterus *r*, vagina *s*, and bladder *t*, is drawn to the right side; the spermatic arteries arise close together but separately in the male Vulpine Phalanger: *f* is the external iliac, corresponding with the common iliac in placental Mammalia, and with the femoral artery in Birds, (see Vol. i. p. 337, *figs.* 170, 23;) below these are given off *h*, the arteries corresponding with the ischiadic arteries in Birds, (Vol. i. p. 337, *fig.* 170, 26,) and with the internal iliacs in Mammalia; [they are represented of too small a size in the cut]; *k* is the femoral artery; *l* the external, *m* the internal branch; *i* is the sacromedian or caudal artery, which is protected in its course along the tail by the hæmapophysial or chevron-like processes of the caudal vertebræ. This artery of course corresponds in size with the developement and functional importance of the tail, and must be rudimentary in the tail-less or nearly tail-less Marsupials, such as the Chœropus, Koala, and Wombat.

With respect to the veins of the Marsupials it may here be noticed that the iliac veins combine to form the trunk of the abdominal cava, as in the rest of the Mammalia, without conveying any part of their blood to the kidneys: in the Kangaroo they both pass on the central aspect of the iliac arteries. The renal veins, in like manner, directly communicate with the abdominal cava, and do not contribute any share in the formation of the portal vein. This great secerning trunk of the hepatic organ presents the strictly mammalian condition, being formed by the reunion of the gastric, intestinal, pancreatic, and splenic veins. It is in the chest that we first meet with decided traces of the oviparous type of structure in the venous system of the Marsupialia. The primitive veins of the animal system of organs, commonly called 'azygos,' retain their original separation and symmetry; the left 'azygos' bends over the left bronchus to communicate with the left anterior cava, and the right azygos over the right bronchus to join the right anterior cava. The left anterior cava commonly

Fig. 134.



Branches of the abdominal aorta, Kangaroo.

receives also the coronary vein of the heart: the termination of this and the two other venous trunks in the right auricle has already been noticed.

Respiratory organs.—In the condition and structure of the respiratory organs all the Marsupial species adhere to the Mammalian type; the only tendency to the Ovipara is in the entireness of the tracheal rings in certain species. In the *Phalangista fuliginosa*, where I counted twenty-nine rings, the first four-and-twenty were entire; below these they were divided posteriorly, the interspace growing wider to the twenty-ninth ring. In the *Dasyurus macrurus* the rings of the trachea are twenty-three in number, and are incomplete or rather ununited behind. In the *Perameles* the tracheal rings are divided posteriorly by a fissure. In no species have I found the trachea divided near the larynx into two long bronchiæ, as in the Rodent genus *Helamys*, nor convoluted in the chest as in the Edentate Sloth, both of which modifications are more striking approximations to the oviparous type of structure than the entire rings above-mentioned.

The *lungs* present the most simple form in the Wombat, in which they consist of a single lobe on both the right and left sides, with a small lobulus azygos extending from the right lung to the interspace between the heart and diaphragm.

In the *Macropus major* I found the right lung with two notches on the anterior margin, and the left lung undivided. In the *Macropus Parryi* both lungs had one or two notches. In another Kangaroo I found the right lung divided into four lobes, the left into two. The azygos lobe is large in consequence of the length of the chest in the Kangaroos, and the distance of the heart from the diaphragm: it is three-sided, one side convex, the second concave and applied to the pericardium, the third side concave, and in contact with the diaphragm.

In the Potoroo the left lung is unilobate with a fissure on the anterior or upper edge; the right lung has two or three deep fissures. The azygos lobe is elongated, pointed, and triedral, as in the Kangaroo.

In the Petaurists and Phalangers the right lung is trilobate, the left bilobate; there is also a lobulus azygos. The Koala has the lungs similarly divided, and not simple as in the Wombat.

In the Opossums, Dasyures, and Perameles the right lung is usually trilobate, (bilobate in *Didelphys brachyura*,) and with the usual azygos appendage: the left lung is commonly divided into two, but is sometimes entire, as in the *Perameles* and *Didelph. brachyura*. In all the Marsupials the right lung is the largest, owing to the oblique inclination of the heart to the left side.

The *thyroid glands* are two disunited bodies in the Dasyures; they were each the size of a horse-bean in the *Das. macrurus*. They were of the same size in a *Phalangista fuliginosa*, but were united by a filamentary strip passing between their lower extremity, across the first tracheal ring. In the Koala, the thyroid gland is situated lower down extending from the fourth to the ninth or tenth tracheal ring. In the Wombat I found the thyroid glands two elongated bodies of a dark colour reaching from the thyroid cartilage to the seventh tracheal ring on each side.

The *larynx* of the Marsupialia consists of a cricoid, thyroid, and arytenoid cartilages and an epiglottis. The latter is always remarkable for its large size, and generally for its emarginate apex. There is no muscle passing from the epiglottis to the tongue; its base is connected in the Kangaroo by a triangular fascia to the body of the os hyoides and the greater cornua; and a small muscle passes from the middle part of the body of the os hyoides to the dorsum linguæ.

In the Phalangers the epiglottis is broad and short, and with a bifid apex. In the Perameles and *Phascogale* the sides of the broad and short epiglottis are attached to the apices of the arytenoid cartilages, retaining thus much of its early condition, which will be adverted to in the account of the peculiarities of the mammary fœtus.

In the *Perameles lagotis* I found on the base of the tongue in front of the epiglottis a small sacculus of mucous membrane, which communicated by a regular symmetrical crescentic aperture, situated between the body of the os hyoides and the thyroid cartilage, and continued down in front of the thyroid cartilage: the surface of the cavity was smooth and lubricated, and it seemed to be for the purpose of facilitating a hinge-like motion between the thyroid cartilage and the body of the os hyoides.

The thyroid cartilage is convex externally and protuberant in the Phalangers and Koala, but offers no particular modification in other Marsupials. The base of the arytenoid cartilages is broad in the antero-posterior direction, and the chordæ vocales short and feebly developed. The Marsupials have little or no voice: the Wombat emits a guttural hissing sound: the *Dasyurus ursinus* a snarling growl or whine: the Thylacine is described as uttering a short guttural cry. I have never heard a vocal note of any kind from the Kangaroos, Potoroos, Petaurists, Phalangers, or Perameles.

Renal system.—The *kidneys* present a simple conglobate external form in all the Marsupials, as in *fig.* 134, *o*, *o*, and in their structure and position in the abdomen agree with the Mammalian type of structure.

In the *Macropus Parryi* the kidneys are situated six inches above the brim of the pelvis, and lying in the same transverse line: they have the same relative position in other Poephaga.

In the Koala the right kidney is higher by its whole length than the left. In the *Dasyuri macrurus* and *viverrinus*, the right kidney lies half an inch higher or in advance of the left: in this carnivorous genus a few branches of the renal veins are distributed upon the surface of the kidney, but not in the same proportion or with the beautiful arborescent disposition characteristic of the kidneys of the Cats, Suricates, and Hyæna. In a *Dasyurus macrurus* weighing three pounds eight ounces, the two kidneys weighed thirteen drachms. In a *Phalangista vulpina*, weighing five pounds three ounces, the two kidneys weighed only ten drachms.

The substance of the kidney is divided into a cortical and medullary part; the former is generally a thin layer. The tubuli uriniferi terminate on a single mammilla which projects into the commencement of the ureter in the Opossums, but does not extend beyond the pelvis of the kidney in the Kangaroos. In the Kangaroos the medullary substance forms several lateral abutments to the base of the main mammilla.

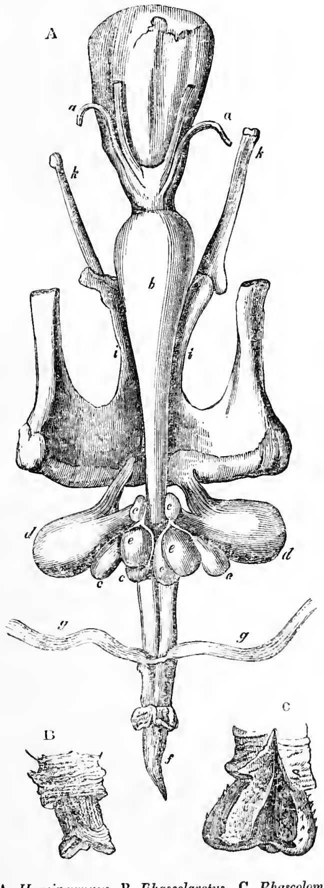
The *supra-renal glands* generally present the relative position and proportions to the kidneys represented in the Kangaroo, at *fig.* 134, *p*. They are, as in most of the smaller quadrupeds, less flat than in man: the right body generally adheres to the coats of the vena cava, and the left to the renal vein. In the Dasyures the external stratum is light-coloured; this surrounds a dark-coloured layer, and then there is a light-coloured central part, but no cavity.

The *ureters* terminate at the back of the neck of a muscular and pendulous urinary bladder (*t*), which only exhibits a trace of urachus at the middle of its anterior part in the young marsupial, while in the maternal pouch.

Male organs of generation.—The testes, which are still abdominal at the time of birth, descend, soon after the fœtus is transferred to the pouch, into the external pedunculate prepenial scrotum; the canal of communication between the abdominal cavity and the tunica vaginalis is long and narrow, but always remains pervious.

The tubuli testis are relatively smaller than in the Rodentia, but are similarly arranged, the corpus Highmorianum being near the surface and upper part, not at the centre, of the gland. The epididymis is large, and generally loosely attached to the testis: in a small species of Kangaroo I found the connecting fold of serous membrane half an inch broad. The vasa deferentia pass from the globus minor along the infundibular muscular sheath formed by the cremaster as far as the abdominal ring, then bend downwards and backwards, and terminate below and external to the ureters, at the commencement of the urethra (*a*, *fig.* 135), on each side a longitudinal verumontanal ridge. There are no vesiculæ seminales in any Marsupial quadruped.

Fig. 135.



A, *Hypsiprymnus*. B, *Phascolarctus*. C, *Phascolomys*.

As the part of the urethral canal immediately succeeding the termination of the vasa deferentia is the analogue of the vagina, some modification of this part might be anticipated in the male corresponding with the extraordinary form and developement which characterise the vagina in the female: accordingly we find that the combined prostatic and membranous or muscular tract of the urethra is proportionally longer and wider in the Marsupial than in any other Mammiferous quadrupeds (*fig.* 135, *b*). It swells out immediately beyond the neck of the bladder, and then gradually tapers to its junction with the spongy part of the urethra: it is not, however, divided like the vagina. Its walls are thick, formed of an external thin stratum of nearly transverse muscular fibres; and a thick glandular layer, the secretion of which exudes by innumerable pores upon the lining membrane of this part of the urethra. In a male Kangaroo I found that a glairy mucus followed compression of this musculo-prostatic tract of the urethra: the canal itself is here slightly dilated.

Three pairs of *Cowper's glands* (*c*, *c*, *c*, *fig.* 135) pour their secretion into the bulbous part of the urethra: the upper or proximal pair are not half the size of the two other pairs in the Kangaroo, but are relatively larger in the Koala and other Marsupials: the two lower pairs are situated, one on each side the lateral division of the bulb of the urethra; their ducts meet and join, above this part, with the duct of the smaller gland: each gland is inclosed by a muscular capsule.

The *penis* consists of a cavernous and a spongy portion, each of which commences by two distinct bodies. The separate origin of each lateral half of the spongy body constitutes a double bulb of the urethra (*e*, *e*, *fig.* 135), and the 'accelerator urinæ,' as it is termed, undergoes a similar division into two separate muscles, each of which is appropriated to compress its particular bulb. The two bulbous processes of the corpus spongiosum soon unite to surround the urethra, but again bifurcate to form a double glans penis in the multiparous Marsupials, in which most of the ova are impregnated in both ovaria, as the Phalangers, Perameles, Opossums, &c. (*b*, *b*, *fig.* 136).

This modification of the opposite extremities of the corpus spongiosum, called 'bulb' and 'glans,' was detected by Cowper in his dissection of a male Opossum; and, in his account of the anatomy of that animal in the Philosophical Transactions for the year 1704, he says, " As the bulb of the urethra in man is framed for the use of the glans, to keep it sufficiently distended when required, so it seems it is necessary to have *two* of these bulbs, inclosed with their particular muscles in this animal, to maintain the turgescence of its *double* or forked glans when the penis is erected."—Vol. xxiv. p. 1585.

The force of this ingenious reasoning on the correlation of the bulb to the glans might seem to be invalidated by the fact that in the uniparous Marsupials, as the Kangaroo, the glans penis (*f*, *fig.* 135) is single, and yet the bulb double:

but in this circumstance we may perceive an example of the retention of a typical structure at the deeper seated part of a system of organs, when not incompatible with a slight modification of a peripheral segment of the same system; it being by no means obviously necessary to abrogate the division of the urethral bulb simply because the blood accumulated in each division was to be driven in a concentrated current upon a single, instead of a double glans penis.

The intermediate structures of the glans between the two extremes above instanced are presented by the Ursine Dasyure, Koala, and Wombat. In the Koala (*fig.* 135, B) the glans penis terminates in two semicircular lobes, and the urethra is continued by a bifurcated groove along the mesial surface of each lobe. In the Wombat (*fig.* 135, C) there is a similar expansion of the urethra into two divergent terminal grooves, but the glans is larger, cylindrical, and partially divided into four lobes:* the chief structure of interest in this part of the Wombat is the callous external membrane of the glans, and its armature of small recurved, scattered horny spines, which do not occur in any other Marsupial animal. The small retroverted papillæ on the infundibuliform glans of the Koala and on the bifurcate glans of the Phalangers and Petaurists are not horny.

In the *Perameles lagotis* not only is the glans bifurcate, but each division is perforated, and the urethral canal is divided by a vertical septum for about half an inch before it reaches the forked glans. From the septum to the bladder the canal is simple, as in other Marsupials. The bifurcations of the glans in the Opossums and Phalangers are simply grooved.

If the experiments of Haighton and the detection, by Drs. Bischoff and Barry, of spermatozoa upon the ovary itself after coitus, had not rendered the question of the necessity of the contact of the semen with the ovarium for impregnation almost independent of the aid of Comparative Anatomy, the differences of structure above described in the urethra and glans penis of the Marsupial animals would have gone far to explode the once prevalent notion of an 'aura seminalis' fertilizing the ovum through the medium of the circulating fluid: for why, on such an hypothesis, should the impregnation of two ovaria, each communicating with a distinct oviduct, uterus, and vagina, as in the Opossum, require two conduits of the semen in the male, one for each vagina?—and wherefore, in the case of an uniparous Marsupial, in which the fecundating stream need ascend only to a single ovarium, as in the Kangaroos and Potoroos, is the penis terminated by a single glans?

The *spermatozoa* of the Perameles have a single barb at the base of the head, which is sub-elongate and compressed; in other respects, as in size and proportion of the filamentary tail, they resemble the spermatozoa of the Rabbit.

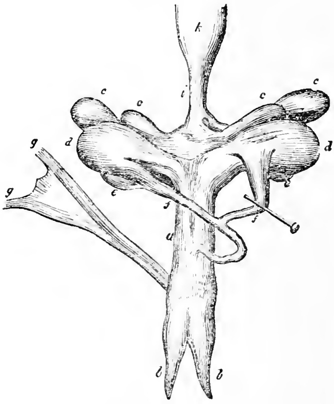
* Cuv. Leçons d'Anat. Comparée, 1805, t. v. p. 91.

Neither in the Kangaroo, Phalanger, nor Dasyure did the spermatozoa present a spiral head or any noticeable deviation from the characters of the spermatozoa in the smaller placental quadrupeds: those of the Dasyure have a node at the base of the head.

The corpus cavernosum penis commences by two crura (*d*, *d*, *figs.* 135, 136), neither of which have any immediate attachment to the bony pelvis. Cuvier correctly states, that in the Kangaroo the two crura of the corpus cavernosum, and the two bulbs of the corpus spongiosum, soon unite to form a single cylindrical body, having a canal which nearly follows the direction of its axis, whose parietes are equally strong and fibrous, and which contains the urethra; so that the transverse section of the corpus cavernosum resembles a ring; but the two lateral cavities are separated by two vertical septa which extend one from the central canal to the dorsum penis, the other from the central canal to the inferior wall of the penis.*

In the Kangaroo and Potoroo, the *erectores penis* (*fig.* 135 *d*, *d*) arise by a thin fascia from near the lower part of the symphysis pubis, soon become fleshy, and increase in thickness as they pass outwards: each muscle then returns upon itself, at an acute bend, to grasp the crus penis, and terminates in a strong tendinous expansion at the junction of the cavernous with the bulbous structure.

Fig. 136.



Male Organs, Opossum.
(Cowper, l. c.)

The *retractor penis* (*figs* 135, 136, *g*, *g*) arises in the Kangaroo from the middle of the sacrum, and divides into two muscles, behind the rectum, opposite the dilated commencement of the musculo-prostatic part of the urethra; each division diverges to the side of the rectum, then passes to the interspace between the rectum and roots of the penis, and along the

* Leçons d'Anat. Comp. 1805, t. v. p. 73.

lateral and posterior part of the penis, until it is inserted with the opposite muscle at the base of the glans.

In the Opossum and those Marsupials which, having a bifid glans, enjoy, as it were, a double coitus, there is a *levator penis* (*f, f, fig.* 136), which is not present in the Kangaroo. Each portion of this muscle takes its origin from the fascia covering the crus penis, converges towards its fellow above the dorsum penis, diminishing as it converges, and terminates in a common tendon inserted into the upper part of the base of the glans.

There is another powerful muscle which, though not immediately attached to the penis, must exert, in all Marsupials, so important an influence upon its erection as to merit notice here. This is the external sphincter ani, or more properly 'sphincter cloacæ:' it is an inch and a half in breadth in the Kangaroo and half an inch in thickness; from the back of the termination of the rectum it passes over the anal glands and sides of the base of the penis, inclosing the two bulbs with Cowper's glands and their muscles, and terminates anteriorly in a strong fascia above the dorsum penis, so as to compress against that part the venæ dorsales.

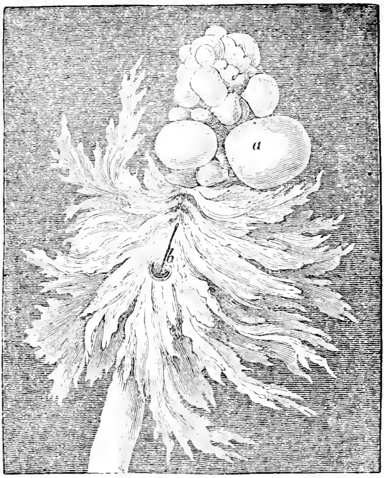
This adjustment and function of the great sphincter did not escape the observation of Cowper. Speaking of the erectores penis of the Opossum, he says, " the muscles of the cavernous bodies of the penis of this creature, having no connexion with the os pubis, cannot apply the dorsum penis to the last-named bone and compress the vein of the penis, whereby to retard the refluent blood and cause an erection, as we have observed in other creatures; but some large veins of the penis here take a different course, and pass through the middle parts of the bulb (crus), and are only liable to the compression made by the intumescence of the muscles (*c c*) that inclose them. But the chief agent in continuing the erection of the penis in this animal is the sphincter muscle of its anus, or rather cloaca; and not only the sphincter muscle of the cloaca of the male Opossum, but that of the female also, closely embraces the penis in coition, and effectually retards the refluent blood from its corpora cavernosa, by compressing the veins of the penis."* The penis is bent upon itself in a sigmoid form when retracted; with the glans concealed just within the cloacal aperture, from which it emerges, as in the Ovipara, when the penis is turgid and erect.

Female organs.—These consist of two ovaries, two oviducts or fallopian tubes, two uteri, two vaginæ, an uro-genital canal, a clitoris, mammary organs, and marsupial pouch.

The *ovaries* are small and simple in the uniparous Kangaroos; tuberculate and relatively larger in the multiparous Opossums; but the largest size and most complicated form of these essential organs which I have met with in the Marsupial order were presented by the Wombat (*fig.* 137). The ovaria are represented of their natural size in *fig.* 138, *a a'*, in the great Kangaroo, where they present an oval form and a smooth unbroken exterior, except after impregnation, when a large corpus luteum projects from the surface, as at *a'*. The ovaria are not inclosed by a capsular duplication of the peritoneum, but are lodged within the expanded orifice of the oviduct, or 'pavilion,' near the upper or anterior extremities of its two principal lobes or processes. These are of considerable extent, and their internal surface, which is highly vascular, is beset with rugæ and papillæ. In the Dasyures and Petaurists the ovaries are elliptical, subcompressed, and smooth. In the Opossum the ovarium consists of a lax stroma remarkable for the number of ovisacs imbedded in it, the largest of which are the most superficial, and give rise to the tubercular projections on the surface of the ovary.

In the Wombat (*fig.* 137) each ovary, besides being lodged in the pavilion, as in the Kangaroo, is inclosed with the pavilion in a

Fig. 137.



Ovarium and pavilion, Wombat. Natural size.

peritoneal capsule. In the unimpregnated female examined by me, the ovaries were six times as large as in the Kangaroo, and presented a well-marked botryoidal form, resembling the ovarium of the bird. Numerous ovisacs in different stages of growth projected from the surface, the largest presenting a diameter of eight lines (*fig.* 137, *a*); the structure of these ovisacs, the character of the stroma in which they are imbedded, and the dense albugineous tunic by which they are inclosed, bespeak the strictly mammalian type of the ovaria of the *Phascolomys* as of every other genus of Marsupial; but the affinity of the Wombat to the Rodent order, in many species of which the ovaria are tu-

Female organs, Kangaroo.

berculate, is again manifested in this part of its structure. The expanded orifices of the fallopian tubes present a greater development than in the Kangaroo, and are still more remarkable for the number, size, and variety of the fimbriated processes and folds which augment the internal vascular surface of the pavilion. In both the Wombat and Kangaroo the lining membrane of the contracted portion of the oviduct is similarly complicated by minute and delicate reticular plications and processes. The oviducts are shorter and less sinuous in their course in the uniparous Kangaroo, *fig.* 138, *b*, than in the multiparous Opossums (*b*, *fig.* 139).

In the above described essential parts of the female generative apparatus the mammalian type of structure is closely adhered to; the deviations most characteristic of the implacental group begin to manifest themselves in the remaining parts, and here under so irregular and complicated a form as to require a brief review of the analogous structures in other groups of animals for their intelligibility.

The variations of structure which the female generative organs present in the oviparous classes of *Vertebrata* are fewer and of less degree than those observable in the different orders and genera of the *Mammalia*. The most prevailing characteristic of the oviparous type of the female generative organs is the absence of union in the mesial plane of the lateral efferent tubes, which consequently continue separate to their terminations in the excretory outlet.

In Birds the genital apparatus is characterised by the higher, and, in the female, as far as function is concerned, exclusive development of the left moiety; and the uniformity in the condition of the excluded ovum in this class corresponds with the sameness which prevails in the structure of the organs concerned in its production.

In Reptiles the ovaries and efferent parts of the genital system are equally developed, or nearly so, on both sides. But although a considerable uniformity of structure is found to prevail in this system throughout the different orders of the class, the widest difference obtains both in the place of development of the ovum and the condition in which it quits its mother. No one, *e. g.*, could have predicated from a comparison of the structure of the ovaries and oviducts in poisonous and innocuous Serpents that any difference existed in the structure and development of the ovum, much less that the former were ovo-viviparous but the latter oviparous; or, from a comparison of the same organs in *Lacerta crocea* and *Lacerta agilis*, that a like difference should exist in the generative economy of species so nearly allied as for a long time to have been confounded together by naturalists.

In *Mammalia*, however, in most of the orders of which the connexion of the ovum with the uterus is so much more intimate than in the preceding classes, the variations in the structure of the female sexual organs are more numerous and remarkable; and though it be admitted that the nature of the fœtal coverings and appendages results from the original constitution and properties of the ovum, yet the modifications of the uterus have evidently, in this class, a subordinate relation to those differences.

In tracing the female generative apparatus from the human subject through the different orders of *Mammalia*, we find that it approximates to the oviparous type of structure in two ways, viz., by an obliteration of the os tincæ, which is the characteristic limit between the uterus and the vagina in this class; and by a gradually increasing division of the uterus and vagina until they become two separate tubes throughout their entire extent.

In no mammiferous genus do the female organs present that character of unity or concentration, with distinction of parts, which is found in the human subject; for in the lower orders, besides the more essential differences above-mentioned, there is always an elongation of the uterus, with a thinning of its parietes, and in general a blending together of the urethral and sexual passages. This latter deviation commences in the *Simiæ*, and in the *Lemures* the angles of the uterus begin to elongate and to assume the form of cornua. The mesial cleft increases, and the cornua preponderate in the *Carnivora*, the *Cetacea*, the *Ruminantia*, and the *Pachydermata*; but it is in the *Rodentia*, which present affinities to Birds in other parts of their structure, that the uterus is first found completely divided into two lateral halves. This structure is not, indeed, uniformly met with in all the genera of the order; but besides the Hare and Rabbit, in which the double uterus is allowed to exist by De Graaf and Cuvier, a similarly complete division of the organ obtains in the genera *Sciurus*, *Arctomys*, *Spalax*, *Bathyergus*, *Echimys*, *Eretizon*, (F. Cuvier) and *Hydrochærus*; while in the genera *Mus*, *Cavia*, *Cœlogenys*, and *Dasyprocta*, a portion of the true uterus still remains undivided; though this part, to which alone the term 'corpus uteri' can be properly applied, is extremely small or rudimental. Nevertheless, although the corpus uteri exists in these genera, the true vagina is as remarkable for its length and capacity as in those in which the corpus uteri has ceased to exist.

Hitherto the vagina has presented itself under the form of a simple undivided canal, communicating with the urethro-sexual passage, at least after impregnation by a single aperture. But it is a remarkable and interesting fact that in the Sloth, in the Mare and Ass, in the Pig, and in the Cow, the vagina in the virgin state communicates with the urethro-sexual passage by a double aperture, in consequence of being traversed by a narrow vertical septum or chord. This septum has been described by veterinary authors as a hymen in the Mare; the analogous part in the human subject also occasionally presents the same structure, and has even been observed in some cases to extend as a mesial partition inwards towards the uterus.

In the *Marsupialia*, where from the small size of the fœtus at birth a similar conformation is permitted to remain as a permanent structure, the vagina is in some genera wholly, and in others partially divided; but the divided portion in the latter is always that which is nearest the urethro-sexual passage.

The true uterus is completely divided in all the Marsupial genera, and each division is of a simple elongated form, as in the *Rodentia*.

The superadded complications in the female generative organs of the *Marsupials*, as compared with other mammals, are not then rightly attributable to the uterus, but to the vagina; and they are of such a nature as to adapt the latter to detain the fœtus, after it has been expelled from the uterus, for a longer period than in other *Mammalia*.

These complications vary considerably in the different marsupial genera. On a comparison of the female organs in *Didelphys dorsigera*, *Petaurus pygmæus*, and *Petaurus taguanoides*, in *Dasyurus viverrinus*, in *Didelphys Virginiana*, in *Macropus major*, and *Hypsiprymnus murinus*, I find that the relative capacity which the uteri bear to the vaginæ diminishes in the order in which the above-named species follow, while the size of the external pouch increases in the same ratio.

In *Didelphys dorsigera* the uteri (*fig.* 139, *c*, *c*,) rather exceed the unfolded vaginæ in

Fig. 139.

Didelphys dorsigera.

length. In most *Marsupials* the vaginæ at first descend as if to communicate directly with the urethro-sexual passage; but in this small Opossum, in which the abdominal pouch consists of two slight longitudinal folds, and the young, as is implied by its trivial name, are transported by the mother on her back, each vaginal tube (*e*, *e*, *fig.* 139,) after embracing the os tincæ (*d*), is immediately continued upwards and outwards, then bends downwards and inwards, and, after a second bend upwards, descends by the side of the opposite tube to terminate parallel with the extremity of the urethra (*h*) in the common or uro-genital passage (*f*).

In the *Petauri*, the vaginæ, when unfolded, are a little longer than the uteri. On examining a specimen of the Pigmy Petaurist which had two very small young in the pouch, I found both the true uteri of three times the diameter of the same in an unimpregnated specimen; but the vaginæ were unaltered in size, indicating that the situation in which gestation takes place in this species is the same as in the Kangaroo. The vaginæ, after receiving the uteri, descend close together half-way towards the commencement of the urethro-sexual passage, but do not communicate together in this part of their course. From the upper part of these culs-de-sac they are continued upwards and outwards, forming a curve, like the handles of a vase, then descend, converge, and terminate close together, as in the preceding example.

In *Dasyurus viverrinus* and *Didelphys Virginiana*, the mesial culs-de-sac of the vaginæ descend to the urethro-sexual passage, and are connected to, but do not communicate with it. The septum dividing them from each other is complete, being composed of two layers which can be separated from each other, and which result indeed from the apposition and mutual cohesion of the vaginæ at this part. In order to reach the common passage, each tube is continued outwards from the upper end of the cul-de-sac, and forming the usual curve, terminates parallel to the orifice of the urethra. The vaginæ in the Dasyures are smaller in proportion to the uteri than in the Virginian Opossum, but of a similar form.

In another species, the *Didelphys Opossum* of Linnæus, it would appear from the description and figures of Daubenton,* that the septum of the mesial culs-de-sac of the vaginæ was imperfect; but it is doubtful whether this intercommunication was not the result of parturition, or of an accidental rupture in the specimen examined. If it should prove to be a specific difference of structure, it is an approximation to the condition of the female organs in the Phalangers, the Wombat, and the Kangaroos.

In the *Macropus major* the vaginæ (*fig.* 138, *e*, *e'*) preponderate in size greatly over the uteri (*c*, *c'*); and, the septum (*e''*) of the descending cul-de-sac being always more or less incomplete, a single cavity (*e*) is thus formed, into which both uteri open; but however imperfect the septum may be, it always intervenes and preserves its original relations to the uterine orifices (*d*, *d*).

The fœtus has been conjectured to pass into the urethro-sexual cavity by a direct aperture formed after impregnation at the lower blind end of the cul-de-sac, but I have not been able to discover any trace of such a foramen in two kangaroos which had borne young; and besides, I find that this part of the vagina is not continuous by means of its proper tissue

* Buffon, Hist. Nat. tom. x. p. 279.

with the urethro-sexual passage, but is connected with it by cellular membrane only; as might have been anticipated from the structure presented in the simpler forms of the marsupial uterus, as in *Didelphys dorsigera* and the *Petauri*, in which the culs-de-sac do not come into contact with the urethro-sexual passage. The evidence of M. Rengger on the development of the young and the parturition of the *Didelphys Azaræ* is also directly opposed to the theory of a temporary orifice in the mesial cul-de-sac.

The last form of the marsupial female organs which may be noticed is that which is found in one species at least of the Kangaroo Rat (*Hypsiprymnus murinus*). The type of construction is, however, the same as in the great Kangaroo, but the mesial cul-de-sac of the vagina attains a still greater development; it not only reaches downwards to the uro-genital passage, but also expands upwards and outwards, dilating into a large chamber, which extends beyond the uteri in every direction. From the sides of this chamber the separated portions of the vagina continue downwards, to terminate, as usual, in the urethro-sexual canal.*

In all the preceding genera the structure of the uteri is as distinct from that of the vaginæ as in the Rodentia. The fibrous or proper tunic of the uteri is thicker than that of the vaginæ, and the lining membrane is soft and vascular, and disposed in numerous irregular folds, which, in section, give apparently a still greater thickness to the uterine parietes. The whole extent of the vaginæ, on the contrary, is lined with a thin layer of cuticle, which is readily detachable, even from the middle cul-de-sac, so generally considered as the corpus uteri in the Kangaroo.

The inner surface of the culs-de-sac in the Opossum is smooth, but in the lower part of the single cavity in the Kangaroo and Potoroo it presents a reticulate structure. The lining membrane in the lateral canals in all the genera is disposed in regular longitudinal folds, a disposition which characterizes the true vagina in most of the ordinary quadrupeds. In the Kangaroo, as in the other Marsupialia, the lateral canals communicate with the common or urethro-sexual cavity without making a projection; but at the distance of three-fourths of an inch from their termination there is a sudden contraction, with a small valvular projection in each (*fig.* 138). By those who consider the cul-de-sac and lateral canals as a modification of the corpus uteri, these projections will probably be regarded as severally representing an os tincæ; but as they do not exist in the Opossums and Petaurists, in which there is simply a contraction of the vaginal canals at the corresponding part, and as in both these and the Kangaroo, the true uteri open in the characteristic valvular manner, as in the *Rodentia*, without the slightest appearance of a gradual blending with the median cul-de-sac, the valvular structure in the lateral canals cannot be regarded as invalidating the view here adopted of the vaginal nature of the median cul-de-sac, which is supported both by the general texture and connexions of the part in question, as well as by what is now ascertained to be its limited function. Moreover, in the large single vagina of some of the *Rodentia*, as the Hare, Rabbit, and Paca, there are two corresponding valvular folds of membrane near its commencement, a little way above the urethral aperture.

In endeavouring to trace the purposes answered by the different forms of the female marsupial organs above described, considerable difficulty arises from the want of the necessary evidence which would be afforded by the examination of the pregnant uterus in each genus, and by the absence of information as to their respective periods of gestation, and the powers of the new-born fœtus. As far, however, as a conclusion can be drawn from the relative periods of gestation in the Kangaroo and Opossum, the proportionate capacities of the vaginæ to the uteri would appear to be greater as gestation is shorter; the vaginæ being thus calculated to present fewer obstacles to the escape of the fœtus in proportion to the duration of its uterine existence; and, consequently, a less capacious and complete external pouch is requisite for its ultimate perfection. From Rengger's description of the connexion of the fœtal Opossum to the uterus, it might be concluded that the generation in that animal approximated to the true viviparous mode more nearly than it does in the Kangaroo; but the determination of this interesting question will require a more exact investigation into the nature of the fœtal vessels and membranes in the genus *Didelphys*. The impregnated uteri of the smaller pouchless Opossums of South America would be objects of peculiar interest and value in the present state of the inquiry.

With respect to the variations of structure in the marsupial female organs, it may also be remarked, that though they are apparently most complicated in the Kangaroos and Phalangers, yet in reality they deviate from the type of the normal *Mammalia* in a minor degree in these *Marsupialia* than in the *Didelphides* and *Petauri*. For, the essential difference being a division of the vagina into two canals, we find this bipartition to be most complete in the multiparous genera, while in the Kangaroos the division is only partial, and the complexity arises from augmented capacity and extent. It is to be observed, however, that the bipartition of the vaginal canal in the Kangaroos is not continued from the uterus into the vagina, leaving its distal extremity single, but commences at the urethro-sexual cavity, and is arrested near the uteri, the orifices of which thus open into a common canal.

The situation of the rudimentary vaginal septum or hymen in the unimpregnated female organs of the placental *Mammalia* before mentioned, corresponds with this formation in the Kangaroo; and in a case where this septum was preternaturally developed in the human subject, it was found to obey the same law of

* See *Philos. Trans.*, 1834, pl. vi. fig. 6.

formation, and at the same time to have been coincident with a completely divided uterus.*

It is not unusual to find the vaginæ of the Kangaroo distended with a gelatino-mucous adhesive secretion containing hard irregularly shaped fibrous masses. One of these bodies, which was found in the mesial cul-de-sac of a Kangaroo, was described and figured by Sir Everard Home† as the vertebral column and occipital bone of a fœtus; and his first theory of marsupial generation appears to have been much influenced by this belief. Professor Leuckart,‡ who found similar bodies in the vaginal tubes of a Kangaroo, compares them to a mola, or false conception, but observes that there was nothing in their structure that would permit him to form a conclusion that they were parts of a fœtus.

In the Wombat the lining membrane of the vaginal culs-de-sac is greatly increased by innumerable irregular rugæ and papillæ, the urethro-sexual canal is lined by a thick epithelium, and its surface is broken into countless oblique rugæ and coarse papillæ; the surface immediately surrounding the urethral orifice, which in this as in other Marsupials is close to the vaginal orifices, is comparatively smooth.

The *clitoris* is situated in a preputial recess near the outlet of the uro-genital passage: it is simple in those marsupials that have a simple glans penis, but is bifid in those which have the glans divided: and in the Opossum each division of the glans clitoridis is grooved.

Development of the Marsupialia.—Before proceeding to detail the present received doctrine of the generation and development of the Marsupialia, it may not be unprofitable to take a rapid glance at the different opinions that have prevailed at different periods respecting this interesting and difficult part of their economy.

The minute size of the young of the American Opossum when first received in the marsupium, their pendulous attachment to the nipples, and perhaps the mode in which the nipples themselves are developed, gave rise, among the earlier observers, to a notion that the young were originally formed by and from those parts.

And this belief was not only current then, as now, among the unscientific settlers in the colonies where the marsupial animals are common, but was entertained likewise by the best informed Naturalists of those times. Thus the learned Marcgrave, in his account of the Opossum, says, when speaking of the marsupial pouch, "*Hæc bursa ipse uterus est Animalis, nam alium non habet, uti ex sectione illius comperi; in hac semen concipitur et catuli formantur.*" § And Piso repeats the assertion more strongly. "*Ex reiteratis horum animalium sectionibus aliam non invenimus uterum præter hanc bursam, in qua semen concipitur et catuli formantur. Quos deinde quinos vel senos simul circumfert, mobiles, perfectos, sed depiles, adeoque pertinaciter uberibus affixos, ut a perpetuo suctu vix avellantur, antequam permittente matre ad pastum ipsi egrediantur.*" *

The assertion that the young grow from the nipple was again repeated in regard to the Philander Opossum (*Didelphys Philander*) by Valentin in his History of Amboyna, and has even been revived at a comparatively recent period.† Some glimpses of the truth were obtained, however, before the time of the authors who have been last quoted. Hernandez, for example, speaks of the generation of the Opossum almost in the same words in which Cuvier‡ sums up the then existing knowledge of the subject in the second edition of his 'Règne Animal.' "Quaternos, quinosve parit catulos, quos *utero conceptos, editosque in lucem*, alvi capacitate quâdam, *dum adhuc parvuli sunt*, claudit ac servat."§ And Maffeius more particularly describes the attachment of the young to the nipple. "Illud autem mirum in Cerigonibus" (Opossums) "ex ejus alvo duæ dependent veluti manticæ, in iis catulos circumfert, et quidem adeo pertinaciter suoquemque uberi affixos, ut a perpetuo suctu non avellantur, antequam ad pastum ipsi per se progredi valeant."||

Nevertheless, as the uterine gestation is here simply alluded to without any detailed observations in proof of it, the assertion was comparatively of little value in a scientific point of view; and the gemmiparous theory, supported by Marcgrave and Piso, seems to have been prevalent at the time when Dr. Tyson first turned his attention to this subject.

The discovery of the true uterus, recorded by that learned and accurate anatomist in the 20th volume of the Philosophical Transactions, p. 105, was the first step towards a correct theory of the generation of the marsupial animals. It necessarily caused him to reject the gemmiparous theory, but, as often happens in such cases, Tyson was led into the opposite or sceptical extreme; and he was also induced to doubt the really accurate statements of Her-

|| Joh. Petr. Maffeius, Hist. Indica.

nandez and *Maffeius* respecting the function of the marsupial pouch; "for," says Tyson, "here I find they place the mammæ or teats, and they tell very odd stories about it," &c.

The female Opossum which *Tyson* dissected appears to have been a young one, and therefore, for a reason which has lately been clearly explained by Mr. Morgan, he was unable to detect the nipples within the pouch, and although he confesses that he was equally unable to find them upon the outer skin, he rejected the statements respecting the premature birth of the young and their pendulous attachment to the nipple, and, believing the generation of the Opossum not to deviate from that of ordinary quadrupeds, he limited the function of the marsupium to that of affording a temporary shelter to the young in time of danger.

The assertions of Hernandez and Maffeius were soon, however, corroborated by other observers; and Daubenton* repeated and confirmed the dissections of Tyson, so far as regarded the existence and general form of the uterus; but no satisfactory explanation was offered as to the nature or precise period of the uterine development or of the passage of the young to the marsupium.

The next really important advance towards the solution of this problem was made by John Hunter, who in the dissection of some marsupial fœtuses of the Kangaroo detected evidences of a deviation from the ordinary mode of mammiferous development, in the absence of the usual traces of a placental organization; there being in these fœtuses no perceptible remains either of an urachus, of umbilical arteries, or of an umbilical vein. The beautiful series of preparations† exhibiting these and other interesting facts in the structure of the mammary‡ fœtus of the Kangaroo are preserved in the Museum of the Royal College of Surgeons, and afforded the principal materials for the paper on Marsupial Generation, published by Mr. (afterwards Sir Everard) Home, in the 85th vol. of the Philosophical Transactions (1795). I have already shewn that one of the chief grounds of the theory of marsupial generation there proposed is untenable, the supposed remains of the fœtus,§ described as being situated in the corpus uteri, (vaginal cul-de-sac,) being nothing more than a portion of the inspissated secretion commonly present both in this sac and the lateral canals. The temporary orifice by which the fœtus is stated to pass immediately from the so called corpus uteri into the vagina (uro-genital passage) does not exist.

In the subsequent theory of marsupial generation propounded by Sir Everard Home,* the 'cornua uteri' of Tyson are regarded as portions of the Fallopian tubes. These he believes to furnish the yelk of the ovum, while the lateral canals, 'uteri reduplicati' of Tyson, secrete the albumen; the ovum is supposed to be impregnated and incubated in the uterus, (middle cul-de-sac formed by the communication of the two vaginal canals,) out of which the young one is stated to pass into the vagina (uro-genital passage) by a particular opening, which prior to gestation does not exist.

The only observations published by John Hunter himself relative to marsupial generation are contained in the 'Zoological Appendix to White's Voyage to New South Wales,' where, in the introduction to his descriptions of the quadrupeds of that country, Mr. Hunter alludes to the American Opossum, and observes, "there is something in the mode of propagation in this animal that deviates from all others; and though known in some degree to be extraordinary, yet it has never been attempted, where opportunity offered, to complete the investigation. I have often endeavoured to breed them in England; I have bought a great many, and my friends have assisted me by bringing them or sending them alive, yet never could get them to breed; and although possessed of a great many facts respecting them, I do not believe my information is sufficient to complete the system of propagation in this class."

At this period, when it was admitted on all hands that some remarkable peculiarities were connected with the marsupial generation, and yet their precise nature and signification remained unelucidated by any direct and accurate observation or experiment, it is not surprising that the subject should have given rise to many curious hypotheses and speculations; those of Sir Everard Home have already been noticed. I shall next briefly allude to the writings of M. Geoffroy St. Hilaire.

The fruitful and discriminating labours of this talented Naturalist in advancing the zoological history of the Marsupialia cannot be too highly esteemed, but his attempts to elucidate their generative economy have been less successful.

Placing an undue reliance on the relation of Count Aboville,† he first revived the gemmiparous doctrine,‡ meeting the objection afforded by Tyson's discovery of an uterus, by the remark that the fœtus of the marsupial animal has never been found there; but that the teats are developed in the ratio of the size and according to the number of the young: that mules equally possess a generative apparatus, which is stricken with sterility: that some plants with a perfect system of procreative organs, nevertheless propagate by gemma-

† See Nos. 3758-3777, Physiol. Catal. vol. v. p. 209.

‡ I adopt this term from M. de Blainville, in preference to the term 'marsupial' previously proposed by Dr. Barton, to express the condition of the young of the Marsupialia from the time they enter the pouch to that of quitting the nipple, or to the close of the period of their uninterrupted attachment to the nipple.

§ No. 3460 F. Physiol. Series, Mus. R. Coll. of Surgeons.

† See the note at the end of the 2d volume of 'Chastelleux Voyage à l'Amerique Septentrionale, Paris, 1786.'

‡ Journal Complementaire du Dict. des Sciences Médicales, 1819.

tion, &c. This theory, however, was abandoned, or at least considerably modified after the publication of Dr. Barton's letters relative to the breeding of the Opossum. The product of marsupial generation is then stated by M. Geoffroy to quit the uterus in the condition of a gelatinous ovulum, comparable to a Medusa, and to become organically connected with the nipple by continuity of vessels. He supposed, therefore, that a flow of blood followed the detachment of the mammary fœtus from the nipple,* and even speculates upon the signification of the thyroid gland, on the strength of this hypothetical confluence of the maternal and fœtal vascular systems in the marsupial tribe.†

In another essay M. Geoffroy abandons this opinion, it having been proved by repeated observation that the adhesion of the fœtus to the nipple is by simple contact merely;‡ and finally, he falls into the opposite extreme, and from some appearances of an urachus which were pointed out to him in a very small fœtus of an American Opossum, he describes them as vestiges of a placental organization.

Mr. Morgan,§ in his elaborate and excellent Memoirs on the Structure and Development of the Mammary Organs of the Kangaroo, bears testimony to the simply mechanical mode of attachment between the mammary fœtus and the nipple in the Kangaroo, and was the first to show that the young animal, in its blind and naked condition, prior to the act of voluntary detachment,—the birth 'à la manière des Marsupiaux,' as it is called by M. Geoffroy,—would bear a separation from the nipple for two hours, and voluntarily regain its hold. The mammary fœtus of the Kangaroo on which Mr. Morgan experimented was nearly the size of a fully grown Norway rat. Mr. Collie, surgeon R.N. in a letter addressed from New South Wales, and published in the Zoological Journal, (No. XVIII. p. 239,) obtained the same result in detaching from the nipple of a smaller species of Kangaroo (*Macropus Brunii*) a mammary fœtus, not two inches in length: he says, "I gently pressed with the tip of my finger the head of the little one away from the teat of which it had hold, and continuing pressing a little more strongly for the space of a minute altogether, when the teat which had been stretched to more than an inch came out of the young one's mouth, and showed a small circular enlargement at its tip, well adapting it for being retained by the mouth of the sucker."

* Geoffroy St. Hilaire, in detailing some observations on a Kangaroo in the 'Annales des Sciences,' observes, "car le sang aperçu à la litière est un indice qu'à ce moment le fœtus s'est detaché de la tetine et qu'il est né définitivement à la manière des marsupiaux." Vol. ix. p. 342, 1827.

† "Des vaisseaux nourriciers se repandroient-ils des parties du pharynx le long et entre les lames de la trachée artère pour entrer le cœur, et (conjecture de M. Serres) le gland thyroide seroit-il le point de leur reunion?" *Geoff. St. Hilaire, Mémoires du Muséum*, tom. xix. p. 406, 1822.

‡ Art. Marsupiaux, Dict. des Sciences Nat. tom. xix. 1823.

§ Transactions of the Linnæan Society, vol. xvi. pp. 61, 455.

—"An hour afterwards the young was observed still unattached, but in about two hours it had hold of the teat, and was actively employed sucking."

Dr. Barton's very interesting observations on the American Opossum are as follows:—"The female *Didelphis Woapink* sometimes produces sixteen young ones at a birth. I have actually seen this number *attached to the teats*, but never a greater number. When they are first excluded from the uterus, they are not only very small but very obscurely shaped. The place of the future eyes is merely marked by two pale bluish specks; we see no ears; in short the animal is a mere mis-shaped embryon. Its mouth, which is afterwards to become very large, is at first a minute hole, nearly of a triangular form, and just of a sufficient size to receive the teat, to which the little creature adheres so firmly, that it is scarcely matter of surprise that Beverly* and other writers have asserted that the young grow fast to the teats.

"It is not true that the young cannot be detached from the mother without the loss of blood; I can assert the contrary from many experiments made upon embryons weighing nine grains and upwards. I have fully satisfied myself as to all the various circumstances, both in the structure and in the exertions of the minute animal, which enable it, while yet a mere speck of living matter, to cling so firmly to the fountain of its support.

"—— The wonderful little Didelphis is by no means the inanimate or the passive being some physiologists and naturalists have represented it.†

"The toes of the fore-feet of the new born embryon opossum are furnished with sharp and hard nails or claws, but this is not the case with the hind-feet. The latter are for some weeks of little use to the animal; but by means of the former it is enabled to cling most firmly to the teat, and especially to the hair in the marsupium immediately around the teat.

"——An opossum-embryon, or fœtus, which weighed sixty-seven grains, lived upwards of thirty hours after I had detached it from the teat. Another which weighed 116 lived thirty-eight hours, at which time I killed it by putting it in spirits.

"Superfœtation (I should perhaps in strict propriety say *uterine* superfœtation) is wholly incompatible with the established laws of the economy of the Didelphis. But Nature, always provident, wastes no time. While, therefore, the first litter of young opossums are fast approaching to their adult state, the mother accepts the ardour of the male; she is impregnated; and after a gestation which is not, I think, remarkably short, if we consider the small size of the embryons when they are excluded from the uterus, the marsupium is destined to perform the office of a second, I was going to say a more important, uterus; just at the time when the first litter have attained such a size that they are no longer (one or two of

* History of Virginia, p. 136, 1722.

† Pennant, Arctic Zool. i. p. 84.

them at the utmost) capable of taking refuge in her pouch." *

Besides the satisfactory evidence, thus afforded by different and independent observers, respecting the condition of the mammary fœtus and its true relations to the nipple, the discovery of the uterine fœtus was announced nearly at the same time by two naturalists in two different species of marsupial animals. Mr. Collie, whose experiment on the young mammary fœtus of a Kangaroo has just been quoted, states in the same letter, " I have just now procured two gravid uteri, (of the *Macropus Brunii,)* in which fœtuses seem to be arrived at, or very near to, the termination of the period of gestation. One of them, which is about the size of the smallest young already mentioned, which was about one-half larger than the body of the common wasp, as being in the abdominal sac, has protruded through an opening inadvertently made in the uterus, and is distinctly seen through its transparent membranes and the liquor amnii."† About the same time Dr. Rengger, a naturalist who was detained several years by the Dictator Francia in Paraguay, gave the following account of the generation of a species of Opossum *(Didelphis Azaræ)* in his work on the Mammalia of that province. " The fœtuses are developed in the cornua uteri, and not in the lateral canals. Some days after impregnation they have the form of small round gelatinous corpuscles, which do not appear, even when examined with a lens, to have any communication with the mother, but a red line indicates the first commencement of development. Towards the end of gestation, when the fœtuses have attained the length of six lines, they are seen to be enveloped in a membrane and provided with an umbilical chord, which is united to the uterus by the medium of many filaments. The head, the four extremities, and tail are recognizable with the naked eye, but those fœtuses which are nearest the Fallopian tubes are generally least advanced. " In gestation they make the circuit of the lateral canals, in which they are found to be deprived of their fœtal envelopes, and to have no communication with the parent by means of the umbilical chord; whilst one fœtus was found in this situation, two others were still in the body of the uterus (vaginal cul-de-sac), from which the umbilical chords were not yet detached. At this period a slight enlargement of the cul-de-sac and lateral canals was the only change perceptible in them."‡

Thus, by the various observations derived from the different sources above indicated, the following propositions are satisfactorily established, viz. that the young of the Marsupialia are developed, primarily, as Tyson conjectured, in the true uteri or cornua uteri; but that, contrary to Tyson's opinion, they are, as compared with other Mammalia, prematurely born; and that, nevertheless, the attachment of the immature young to the nipple is essentially the same as in ordinary mammals, the young marsupial being nourished by the lacteal secretion, and its blood aerated by its own independent respiratory actions.

Such, therefore, being the condition of the problem of marsupial generation in the year 1830, there remained to be determined by exact experiment and observation the period of uterine gestation, the structure of the fœtal envelopes and appendages, the nature of the connection, if any, between the uterine fœtus and the womb, the manner of the uterine birth, and the condition and powers of the new-born young.

With a view to the solution of these questions, I applied for and obtained from the Council of the Zoological Society permission to perform the requisite experiments on the Kangaroos in the menagerie in Regent's Park. A healthy female *(Macropus major*, Shaw) was separated from the rest; she had a young one which measured about one foot two inches from the nose to the root of the tail, and which continued to return to the pouch for the purpose of sucking and for shelter. The right superior nipple was the one in use; it was nearly two inches long, and one-third of an inch in diameter; the mammary gland formed a large swelling at its base. The other three nipples were everted, and about half-an-inch in length.

A healthy full-grown male was admitted into the paddock with this female for a certain period each day, and watched, during that time, by the keeper or myself. In the course of a week the female seemed to be in a condition to excite the sexual ardour, and after a few days toying on the part of the male, she received his embrace on the 27th August, at 1 p.m. The female stood with her fore-paws off the ground, the male mounted, '*more canino*,' embracing her neck with his fore-paws, and retained his hold during a full quarter of an hour; during this period the coitus was repeated three times, and on the second occasion much fluid escaped from the vulva. The male was removed from the female in the evening of the same day, and was not afterwards admitted to her. On September the 2d, six days after the coitus, I examined the pouch of the female, and this scrutiny was repeated every morning and evening until the birth of the young kangaroo had taken place. I select the following from the notes taken on those occasions:—

" Sept. 6th.—10th day of gestation. The pouch is nearly free from its peculiar brown musky secretion. The right superior nipple retains its large size, and the young one that has left the pouch returns occasionally to suck.

" Sept. 11th.—15th day of gestation. No appearance of a mammary fœtus; nipples in the same condition; the young kangaroo continues to suck and return to the pouch for shelter.

" Sept. 30th.—34th day. The nipple in use by the young kangaroo (which has died) is diminished in size, and the brown secretion

* Barton, ' Facts, Observations, and Conjectures relative to the Generation of the Opossum.' Annals of Philosophy, vol. vi. 1823, p. 349.

† Zoological Journal, vol. v. p. 240.

‡ From the Analysis of Rengger's " Saugethiere von Paraguay" in the Bulletin des Sciences Nat. tom. xxi. p. 469.

has begun to be formed. Qy.—Will the fœtus seize the larger nipple as the readiest, or be directed to another more proportionate to the size of its mouth?

"Oct. 4th.—38th day. The keeper has observed the female putting her nose into the pouch, and licking the entry. She was examined at six in the evening; there was a slight increase of the brown secretion; the nipple formerly in use has diminished one-third in size; the other nipples indicate no appearance of approaching parturition.

"Oct. 5th.—39th day. The keeper examined the pouch at seven this morning, and found there the young one attached to a nipple. On being made acquainted with this fact I repaired to the Zoological Gardens, and examined the pouch. The new-born kangaroo (*fig.* 140) was attached to the left superior nipple (*fig.* 140, *a*), to the point of which it adhered pretty

Fig. 140.

New-born fœtus and left nipples, Macropus major.

firmly. It measured one inch from the mouth to the root of the tail, was quite naked, and covered by a thin semitransparent vascular integument; the place of attachment of the umbilical chord was obscurely indicated by a longitudinal linear cicatrix. The fore-legs were longer and stronger than the hind ones, and the digits were provided with claws; the toes were developed on the hind legs; the body was bent forward; and the short tail tucked in between the hind legs. This little animal breathed strongly, but slowly; no direct act of sucking could be perceived. Such, after a gestation of thirty-eight days, is the condition of the new-born young of a species of Kangaroo, of which the adult, when standing erect on his hind feet and tail, can reach to the height of seven feet. The birth having taken place in the night, the mode of transference of the young to the pouch and nipple was not observed.

The hypothesis of an internal passage from the uterus to the pouch — countenanced by some imperfect anatomical observations on the course of the round ligament to the abdominal ring, and the continuation thence of the cremaster to the posterior part of the mammary gland, together with the primitive inverted condition of the nipple—is wholly refuted by more exact observations of the conditions of these parts. I was chagrined at the loss of so favourable an opportunity of determining, *ex visu*, this interesting part of the problem; for it had been my intention, if the symptoms of approaching pregnancy had been more marked, to have established a night as well as day-watch over the female; but by placing perhaps too much reliance on the observations on the pregnant kangaroo recorded in the 9th volume of the Annales des Sciences, in which the duration of four months is assigned to the uterine gestation of this species, I had not anticipated so speedy a termination of that process as resulted from my experiment.

In order, however, to remedy, as far as might be, this omission, it occurred to me that if the young kangaroo were detached from the nipple and deposited at the bottom of the pouch, any actions of the parent, by which its original transference from the uterus to the nipple had been aided or effected, might be instinctively repeated, and thus an insight be gained into their nature. As, therefore, the experiments of Messrs. Morgan and Collie seemed to show that this might be done without necessarily causing the death of the young one, I performed the experiment with the sanction and assistance of Mr. Bennett, then Secretary of the Zoological Society.

"Oct. 9th.—I examined the pouch of the female, and found the young one, now four days old, evidently grown, and respiring vigorously; it adhered more firmly to the nipple than was expected, requiring a continued gentle pressure to detach it: when that took place, a minute drop of whitish fluid, a kind of serous milk, was expressed from the nipple. No blood followed, nor anything to indicate a solution of organic continuity; the extremity of the nipple was small, not swollen as in Mr. Collie's case. The young one moved its extremities vigorously. It was deposited at the bottom of the pouch, and the mother was left and then carefully watched. Soon after this was done she seemed uneasy, was often scratching the exterior of the pouch, and every now and then dilated the cavity with her two fore-paws, grasping the sides of the aperture, and pulling them in contrary directions, just as in drawing open a bag; she then inserted her muzzle pretty deeply into the pouch, moving her head about as if to lick off something from the interior, or perhaps to move the little one. She kept her nose in the pouch sometimes for half-a-minute. I never observed her to put her fore-legs, or either of them, in the pouch; they were always occupied in keeping open the mouth of the pouch, while she was at work with her mouth within it. She generally concluded by licking the mouth of the pouch, and occasionally she stooped down to lick the cloaca, which she could reach with ease. When she scratched the outside of the pouch it seemed as if to push up something that was inside towards the aperture. These actions she repeated at short intervals for about an hour; she then lay down and appeared quiet. She had also lain down in the intervals of the above operation, but during that time never meddled with the pouch; when stimulated to do so by some uneasy sensation, she always rose upon her hind feet, and then inserted her muzzle alternately into the pouch and vulva. Observing the freedom with which she could reach both these parts, I was led to believe that the mode of removal of the young from the vulva to the pouch was by the mouth of the mother. Her fore-paws, in this case, would be used, not for the transport of the young, but for keeping the mouth of the pouch open for its reception, it being deposited therein by the mouth, and so held over a nipple until the mother had felt it grasping the sensitive extremity of the nipple.

This means of removal is consistent with analogy; dogs, cats, mice, all transport their young from place to place with the mouth. In the case of the kangaroo, it may be supposed that the fœtus would be held by the lips only, not the teeth, on account of its delicate consistence. Whether this theory, suggested by witnessing the actions of the mother after an artificial separation of the Marsupial fœtus, be correct, must be confirmed by actual observation. There is no internal passage from the uterus to the pouch:—the mouth of the vagina cannot be brought into contact with that of the pouch, either by muscular contraction in the living or by any force of stretching in the dead kangaroo:—as the young was proved by the result of this experiment not to have the power of itself to regain the nipple, *à fortiori* we may conclude that it could not transfer itself from the vulva to the interior of the pouch and to the apex of the nipple:—the fore-paws of the Kangaroo would not so effectually protect the tender embryo from the external air as the mouth, nor so safely ensure its passage to the pouch, notwithstanding that they are adroitly used in grasping objects, being similar, in respect of the extent and freedom of motion of the digits, to the fore-paws of the Rodents.

After the mother had rested quietly for a short time, we again examined her, but found the young one still detached, moving more vigorously than before. On an examination two days afterwards the marsupium was found empty: the young one had died and had probably been removed by the mother.

Thus the period of uterine gestation, the condition of the new-born young, and the probable mode of its transference to the nipple being determined in the genus *Macropus*, it next remained to be determined how the embryo was nourished in utero. The means of giving the required solution were shortly after afforded by specimens of the impregnated uterus, transmitted to me by Mr. George Bennett, Captain Grey, and Dr. Sweatman. The first was of the *Macropus major*, nearly two-thirds of uterine gestation having been completed; the second was of the *Macropus penicillatus*, at about the same or somewhat earlier period of gestation; the third exhibited the uterine fœtus at nearly the completion of that period of its existence.

Before, however, giving the summary of what I have elsewhere* recorded respecting the uterine development of the Marsupialia, a description of the ovarian ovum must be premised.

In the Kangaroo this part agrees in all essential points with the observed ovarian ova of placental Mammalia: the main modification is the greater proportion of vitelline fluid and globules, and the smaller proportion of fluid between the external membrane of the ovum (vitelline membrane) and the ovarian vesicle, or lining membrane of the ovisac.

In a female *Macropus Parryi*, the ovum from the largest ovisac of the left ovarium measured $\frac{1}{10}$th of a line in diameter, the germinal vesicle $\frac{1}{140}$th of a line in diameter.

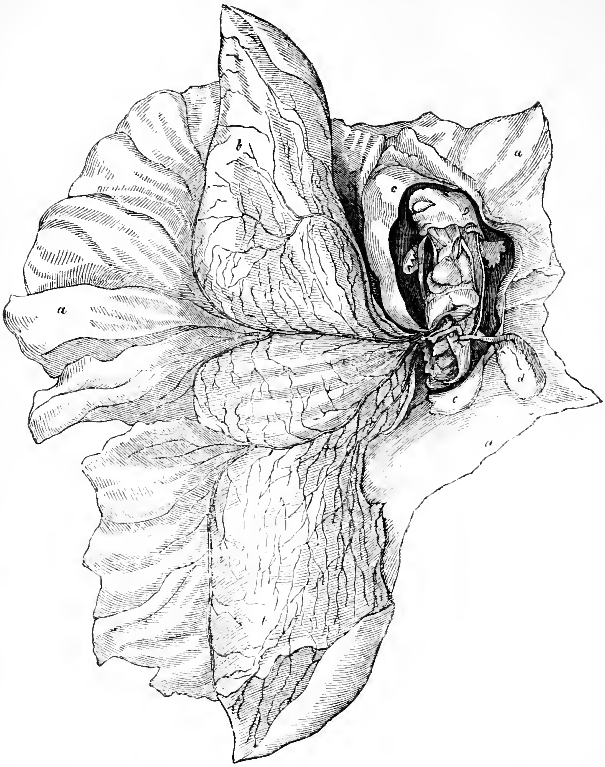
We are at present ignorant of the changes that take place in the development of the ovum between the period of impregnation until about the twentieth day of uterine gestation. At this time, in the great Kangaroo (*Macropus major*), the uterine fœtus (*fig.* 138) measures eight lines from the mouth to the root of the tail; the mouth is widely open (*fig.* 141); the tongue large and protruded; the nostrils are small round apertures; the eyeball not yet wholly defended by the palpebral folds; the meatus auditorius externus is not provided with an auricle; the fore-extremities are the largest and strongest; they are each terminated by five well-marked digits; those of the hind legs are not yet developed; the cervical fold of the mucous layer or the branchial fissure is still unenclosed by the integument. The tail is two lines long, thick and strong at the commencement; impressions of the ribs are visible at the sides of the body; the membranous tube of the spinal marrow may be traced along the back between the ununited elements of the vertebral arches; posterior to the umbilical chord there is a small projecting penis, and behind that, on the same prominence, is the anus. This fœtus and its appendages were enveloped in a large chorion, puckered up into numerous folds, some of which were insinuated between folds of the vascular lining membrane of the uterus, but the greater portion was collected into a wrinkled mass. The entire ovum was removed without any opposition from a placental or villous adhesion to the uterus. The chorion (*a*, *a*, *fig.* 141) was extremely thin and lacerable; and upon carefully examining its whole outer surface, no trace of villi or of vessels could be perceived. Detached portions were then placed in the field of a microscope, but without the slightest evidence of vascularity being discernible. The next membrane, whose nature and limits will be presently described, was seen extending from the umbilicus to the inner surface of the chorion, and was highly vascular. The fœtus was immediately enveloped in a transparent amnios.

On turning the chorion away from the fœtus, it was found to adhere to the vascular membrane above-mentioned, into which the umbilical stem suddenly expanded. With a slight effort, however, the two membranes could be separated from each other, without laceration, for the extent of an inch; but at this distance from the umbilicus the chorion gave way on every attempt to detach it from the internal vascular membrane, which here was plainly seen to terminate in a well-defined ridge, formed by the trunk of a bloodvessel.

When the whole of the vascular membrane

* Proceedings of the Zool. Society, 1833. Philos. Trans. 1834.

Fig. 141.



Uterine fœtus with chorion and fœtal appendages, Macropus major. The fœtus is magnified twice the natural size.

(*b, fig.* 141) was spread out, its figure appeared to have been that of a cone, of which the apex was the umbilical chord, and the base the terminal vessel above-mentioned. Three vessels could be distinguished diverging from the umbilical chord and ramifying over it. Two of these trunks contained coagulated blood, and were the immediate continuations of the terminal or marginal vessel: the third was smaller, empty, and evidently the arterial trunk. Besides the extremely numerous ramifications dispersed over this membrane, it differed from the chorion in being of a yellowish tint. The amnios (*c*, 141) was reflected from the umbilical chord, and formed, as usual, the immediate investment of the fœtus.

The umbilical chord measured two lines in length and one in diameter. It was found to contain the three vessels above-mentioned, with a small loop of intestine; and from the extremity of the latter a filamentary process was continued to the vascular membrane. The margins of the umbilicus or abdominal opening were very strong, offering much resistance to their division. On tracing the contents of the chord into the abdomen, the two larger vessels with coagulated blood were found to unite; the common trunk then passed backwards beneath the duodenum, and after being joined by the mesenteric vein, went to the under surface of the liver, where it penetrated that viscus: this was consequently an omphalo-mesenteric or vitelline vein. The artery was a branch of the mesenteric. The membrane, therefore, upon which they ramified, answered to the vitellicle, i. e. the vascular and mucous layers of the germinal membrane, which spreads over the yolk in oviparous animals, and which constitutes the umbilical vesicle of the embryo of ordinary Mammalia. The filamentary pedicle which connected this membrane to the intestine was given off near the end of the ileum, and not continued from the cœcum, the rudiment of which was very evident half a line below the origin of the pedicle. (See the fœtus in *fig.* 141.)

The small intestine above the pedicle was disposed in five folds. The first from the stomach or duodenum curved over the vitelline vein, and the remaining folds were disposed around both the vitelline vessels. From the cœcum, which was given off from the returning portion of the umbilical loop of the intestine, the large intestine passed backwards to the spine, and was then bent, at a right angle, to go straight down to the anus. The stomach did not present any appearance of the sacculated structure so remarkable in the adult, but had the simple form of a carnivorous stomach. The liver consisted of two equal and symmetrically disposed lobes. The vena portæ was formed by the union of the vitelline with the mesenteric, and doubtless the other usual veins, which were, however, too small to be distinctly perceived. The diaphragm was perfectly formed.

The vena cava inferior was joined, above the diaphragm, by the left superior cava, just at its termination in a large right auricle. The ventricles of the heart were completely joined together, and bore the same proportions to each other as in the adult,—a perfection of structure which is not observed in the embryos of ordinary *Mammalia* at a corresponding period of development. The pulmonary artery and aorta were of nearly the same proportionate size as in the adult: the divisions of the pulmonary artery to the lungs were at least double the size of those observable in the embryo of a sheep three inches in length. The ductus arteriosus, on the contrary, was remarkably small. The aorta, prior to forming the descending trunk, dilated into a bulb, from which the carotid and subclavian arteries were given off.

The lungs were of equal size with the heart, being about a line in length, and nearly the same in breadth: they were of a spongy texture and of a red colour, like the veins, from the quantity of blood they contained. This precocious development of the thoracic viscera is an evident provision for the early or premature exercise of the lungs as respiratory organs in this animal: and on account of the simple condition of the alimentary canal, the chest at this period exceeds the abdomen in size.

The kidneys had the same form and situation as in the adult. The supra-renal glands were half the size of the kidneys.

The testes were situated below the kidneys, and were one-half larger than those glands, the superiority of size depending on their large epididymis, with the adherent remains of the Wolffian body. They continue within the abdomen for six weeks after uterine birth.

At a later period of uterine development, when the fœtus, measured in a straight line from the mouth to the root of the tail, is ten lines in length, the urachus expands into a small allantois (*d*, *fig.* 141), of a flattened pyriform figure, and finely wrinkled external surface. This bag insinuates itself between the amnios and chorion, carrying along with it two small hypogastric arteries and an umbilical vein, but not establishing by their means an organized and vascular surface of the chorion by which a placental attachment is formed between the ovum and the womb. The allantois depends freely from the end of the umbilical chord, and has no connexion at any part of its circumference with the adjoining membrane. Its office is apparently that of a receptacle of urine.

The vitellicle or umbilical sac presented the same large proportionate size and vascular structure as in the first described fœtus. The chorion which enveloped this fœtus and its appended sacs was adapted to the cavity of the uterus by being disposed in innumerable folds and wrinkles. It did not adhere at any part of its surface to the uterus, but presented a modification not present in the chorion of the earlier fœtus, in being partially organized by the extension of the omphalo-mesenteric vessels upon it from the adherent vitellicle. The digits of the hind legs were distinctly formed in this embryo.

The new-born fœtus of the great Kangaroo does not exceed, as we have already shown, one inch in length; its external characters have been already described. Dr. Barton has given the following account of the Opossum (*Didelphys Virginiana*) at an analogous period. "I have been so fortunate as to ascertain the size and weight of several embryos immediately after their exclusion from the uterus. One of them weighed only one grain! The weight of each of the six other young ones was but little more than this. The young opossums, unformed and perfectly sightless as they are at this period, *find* their way to the teats by the power of an invariable, a *determinate* instinct" (qu.?). "In this new domicilium they continue for about fifty days, that is, until they attain the size of a common mouse (*Mus musculus*), when they begin to leave the teats *occasionally*, but return to them again until they are nearly the size of rats.

"At the end of about fifty or fifty-two days from its first reception in the pouch the eyes of the young begin to open.

"I have found that the same embryon has increased in weight 531 grains in sixty days, that is, at a rate of almost 9 grains daily. The animal attains to nearly its full growth in about five months; but never, I believe, (in our latitudes I mean,) procreates the first year of its existence.

"On the 21st of May, upon looking into the box which contained the female Opossum, I found that she had just excluded from her uterus seven embryons; the smallest of which scarcely weighed one grain, another barely two grains, and the remaining five (taken together) exactly seven grains."*

In the Kangaroo about ten months elapse before the mammary fœtus quits the pouch: it has, prior to this period, quitted the nipple,

* Barton, in Annals of Philosophy, vi. (1823), p. 349. "*Facts, Observations, and Conjectures relative to the Generation of the Opossum.*"

and occasionally protrudes its head and changes its position in the pouch.

The anatomical condition and progressive development of the mammary fœtus of the Marsupialia offer a subject of highly interesting research, especially if compared with the same circumstances in the uterine fœtus of an equal sized and analogous placental species. Much still remains to be done in this chapter of the history of Marsupial generation; at present I have to offer the following observations.

By comparing the new-born Kangaroo with a similarly sized fœtus of a sheep, we find that, although, in the Kangaroo, the ordinary laws of development have been adhered to in the more advanced condition of the anterior part of the body and corresponding extremities, yet that the brain does not present so disproportionate a size; and the same difference is observable in the uterine fœtus of the Kangaroo, even when compared with the same sized embryo of an animal of an inferior class, as the bird. This difference, I apprehend, is owing to the rapidity with which the heart and lungs acquire their adult structure in the Kangaroo, whereby the passage of the purer and more nutritious blood through the foramen ovale and left auricle to the primary branches of the aorta and so to the brain is impeded. The brain, however, of the mammary fœtus, though exhibiting a low degree of development, yet is of a firmer texture than in a similarly sized fœtus of a sheep, and attains its ultimate proportion by a more gradual process of growth.

In a mammary fœtus, one inch and a half in length, the urinary bladder is largely developed, and adheres by its apex to the peritoneum, exactly opposite that part of the abdominal integument where a small linear ridge indicated the previous attachment to the umbilical chord and appendage. There are also minute but distinct traces of umbilical arteries running up the sides of the bladder to this point of attachment. As the urinary bladder becomes afterwards expanded in the abdomen, the peritoneum is gradually, as it were, drawn from this part of the abdominal parietes, forming an anterior ligament of the bladder. In a mammary fœtus of the Kangaroo about a month older than the above, there was at the superior part of this duplicature a small projecting point from the bladder, like the remains of a urachus; but the fundus, now developed considerably above this point, was covered with a perfectly smooth layer of peritoneum; and it is this modification, I apprehend, which led Hunter to suppose that there was no trace of urachus or umbilical arteries in the fœtuses of the *Marsupialia*. In the Sloth, the Manis, and the Armadillo, the urachus is continued in the same manner from the middle of the anterior part of the bladder, and not from the fundus.

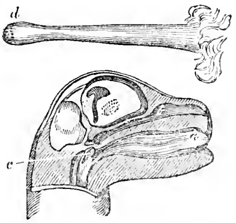
In neither of the above fœtuses of the Kangaroo was there any corresponding trace of umbilical vein, although there was a distinct ligamentum suspensorium hepatis, formed by a duplicature of the peritoneum descending from the diaphragm to the notch lodging the gall-bladder, and not entering, as usual, the fissure to the left of that notch: the allantois is too small, and its function too limited for the preservation of any permanent trace of its peculiar vein.

The small intestines in the mammary fœtus, one inch and a half long, when compared with those of the uterine fœtus above described, were found to have acquired several additional convolutions; the fold to which the umbilical vesicle had been attached was still distinct, but now drawn in to the back of the abdomen. The cœcum was much elongated, but the colon proportionately not more developed than in the uterine fœtus; the subsequent modification, therefore, of the large intestines seems evidently destined to complete the digestion of the vegetable food.

The stomach was not sacculated, but the division between the cardiac and middle compartments was more marked than in the uterine fœtus. The liver had now advanced in its development beyond the oviparous form which it presented in the uterine fœtus, the right lobe being subdivided into three. The supra-renal glands bore the same proportionate size to the kidneys. The testes were still larger than the kidneys, and were situated below them, not having yet passed out of the abdomen: this takes place when the mammary fœtus is about three inches long from the nose to the root of the tail. The ductus arteriosus was distinct in the small mammary fœtus, but I could not perceive any trace of the thymus gland. Is this gland unnecessary on account of the precocious development of the lungs? or because of the small size and gradual growth of the brain? The latter appears the more probable condition of its absence, as in the ovoviviparous classes with small and simple brains the thymus gland is rudimental or of doubtful existence.

Notwithstanding that the new-born Kangaroo possesses greater powers of action than the same sized embryo of a sheep, and approximates more nearly in this respect to the new-born young of the rat, yet it is evidently inferior to the latter. For, although it is enabled by the muscular power of its lips to grasp and adhere firmly to the nipple, it seems to be unable to draw sustenance therefrom by its own unaided efforts. The mother, as Professor Geoffroy and Mr. Morgan have shown, is therefore provided with the peculiar adaptation of a muscle (analogous to the cremaster) to the mammary gland, for the evident purpose of injecting the milk from the nipple into the mouth of the adherent fœtus. Now it can scarcely be supposed that the fœtal efforts of suction should always be coincident with the maternal act of injection; and if at any time this should not be the case, a fatal accident might happen from the milk being forcibly injected into the larynx, unless that aperture were guarded by some special contrivance. Professor Geoffroy first described the modification by which this purpose is effected; and Mr. Hunter appears to have anticipated the necessity for such a structure, for he dissected two small mammary fœtuses of the Kangaroo for the especial purpose of showing the relation of the larynx to the posterior nares. The epiglottis and arytenoid cartilages are elongated and approximated, and the rima glottidis is thus situated at the apex of a cone-shaped larynx, (*fig.* 142, *c*,) which projects, as in the *Cetacea*, into the posterior nares, where it is closely embraced by the muscles of the soft palate. The air-passage (*b*) is thus completely separated from the fauces, and the injected milk passes in a divided stream on either side the larynx to the œsophagus.

Fig. 142.



Nipple, and head of Mammary Fœtus, Kangaroo.

Thus aided and protected by modifications of structure, both in the system of the mother and its own, designed with especial reference to each other's peculiar condition, and affording, therefore, the most irrefragable evidence of creative foresight, the small offspring of the Kangaroo continues to increase, from sustenance exclusively derived from the mother, for a period of about eight months. During this period the hind legs and tail assume a great part of their adult proportions; the muzzle elongates; the external ears and eyelids are completed; the hair begins to be developed at about the sixth month. At the eighth month the young Kangaroo may be seen frequently to protrude its head from the mouth of the pouch, and to crop the grass at the same time that the mother is browsing. Having thus acquired additional strength, it quits the pouch and hops at first with a feeble and vacillating gait, but continues to return to the pouch for occasional shelter and supplies of food till it has attained the weight of ten pounds. After this it will occasionally insert its head for the purpose of sucking, notwithstanding another fœtus may have been deposited in the pouch; for the latter, as we have seen, attaches itself to a different nipple from the one which had been previously in use.

Mammary Organs.—In the young Marsupial, as Mr. Morgan was the first to observe in the Kangaroo, the nipples are not visible, but are indicated by the orifices of a kind of cutaneous preputial sheath in which they are concealed. M. Laurent has noticed a similar condition of the nipples in a mammary fœtus of an Opossum and a Perameles. I have also observed it in the mammary fœtus of a Petaurist and Dasyure: it is doubtless, therefore, common to all Marsupials.

Once naturally protruded and the preputial sheath everted, the nipples, in the Kangaroo at least, continue external. They are longer and more slender than in other quadrupeds, and when in use generally present a terminal expansion (*fig.* 142, *d*). This part lies in a deep longitudinal fossa on the dorsum of the tongue (*a*, *fig.* 142); and the originally wide mouth of the uterine fœtus is changed to a long tubular cavity, with a terminal subcircular or triangular aperture just large enough to admit the nipple, to which the young Marsupial thus very firmly adheres.

In the Phascogale, in which the nipples are relatively larger than usual, and of a subcompressed clavate form, the young, when grown too large to be carried in the pouch, are dragged along by the mother, if she be pursued, hanging by the nipples.

The number of nipples bears relation in the marsupial, as in the placental Mammalia, to that of the young brought forth at a birth; although from the circumstance of the produce of two gestations being for a short time suckled simultaneously, the nipples are never so few. Thus the uniparous Kangaroo has four nipples; of which the two anterior are generally those in use: the Petaurists, which bring forth two young at a birth, have also four nipples: the Thalycine has four nipples: the multiparous Virginian Opossum has thirteen nipples, six on each side and the thirteenth in the middle. In the *Didelphys Opossum* there are nine nipples, four on each side and one in the middle. The *Didelphys dorsigera* has the same number of nipples, although six is the usual number of young at a birth (*fig.* 143). In the *Phascogale penicillata* there are eight nipples arranged in a circle. The *Perameles nasuta* has the same number of nipples arranged in two slightly curved longitudinal rows; this Marsupial has three or four young at a birth.

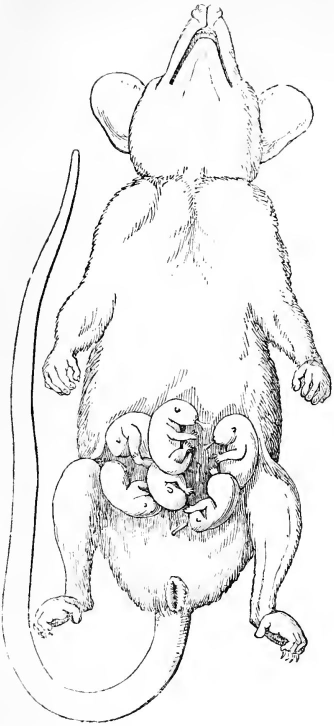
The nipple in all the Marsupials is imperforate at the centre; the milk exudes from six to ten minute orifices arranged round the apex. It increases in size with the growth of the mammary fœtus appended to it.

The mammary gland has the same essential structure as in the ordinary Mammalia; it has no cavity or udder; its chief peculiarity arises from its being embraced by the muscle, already noticed, which has the same origin and course as the cremaster muscle in the male.

Marsupial pouch.—The development of the pouch is in an inverse ratio to that of the uteri and directly as that of the complicated vaginæ: thus it is rudimental in the Dorsigerous Opossum, which has the longest uteri and the simplest vaginæ: we may conclude therefore that the young undergo a greater amount of development in the womb in this and allied species.*

* Is there any essential modification of the membranes of the ovum in these small Marsupials? The means of determining this question are most desirable.

Fig. 143.



Female Didelphys dorsigera, with young and pouch.

In the Kangaroos and Potoroos, which have the shortest uteri and longest vaginal tubes and cul-de-sac, the marsupial pouch is wide and deep. It is composed of a duplicature of the integument, of which the external fold is supported by longitudinal fasciculi of the panniculus carnosus converging below to be implanted in the symphysis pubis. The mouth of the sac is closed by a strong cutaneous sphincter muscle. The interior of the pouch is almost naked: a few hairs grow around the nipple: it is lubricated by a brown sebaceous secretion. The mouth of the pouch is directed forwards in most Marsupials: the reversed position in the Perameles and Chæropus, where the mouth is directed towards the vulva, has been already noticed. M. Laurent* has made the interesting observation of the presence of a rudimental pouch in the male mammary fœtus of an Opossum: he could not discern equal traces of the nipples: that of the pouch is soon obliterated, as the scrotum increases in size.

In the male Thylacine the rudimental marsupium is retained, in the form of a broad triangular depression or shallow inverted fold of the abdominal integument, from the middle of which the peduncle of the scrotum is continued. In the female the orifice of the capacious pouch is situated nearer the posterior than the anterior boundary of that receptacle.

A few observations on the claims of the Marsupialia to be regarded as a natural group of animals may not inappropriately conclude this article. Cuvier, in 1816, first separated the marsupial from the other unguiculate quadrupeds, to form a distinct group, which he describes as forming, with the Monotremes, a small collateral chain, all the genera of which, while they are connected together by the peculiarities of the generative system, at the same time correspond in their dentition and diet, some to the Carnivora, others to the Rodentia, and a third tribe to the Edentata. M. de Blainville, in the tables of the Animal Kingdom which he published in the same year, 1816, constituted a distinct sub-class of Cuvier's " small collateral chain " of mammals, and gave to the sub-class the name of *Didelphes* in antithesis to that of *Monodelphes*, by which he distinguished the Placental Mammalia.

The class or sub-class 'Implacentalia,' of which the *Marsupialia* form one order, also includes a second order, the *Monotremata*, which can only be termed 'Didelphes' in the sense in which the word is applicable to many of M. de Blainville's 'Monodelphes,' i. e. in reference to their having two distinct uterine tubes. But the merit of the primary division of the Mammalia into PLACENTALIA and IMPLACENTALIA does not rest upon the appropriateness of the terms, but upon the establishment, by a long series of anatomical researches, of a primary division of the Mammiferous class, which before was a mere hypothesis.

Many acute and sound-thinking naturalists refused their assent to the views of Cuvier and De Blainville, which, as they were supported by a knowledge of the conformity of organization of only the generative system in the Marsupials, were unquestionably defective in the evidence essential to enforce conviction. The best arguments for returning to the older views of classification, and for distributing the Marsupial genera, according to the affinities apparently indicated by their dental and locomotive systems, among the different orders of the Placental Mammalia, have been advanced by Mr. Bennett, the accomplished author of the *Gardens and Menagerie of the Zoological Society delineated*, (vol. i. p. 265); and these have been repeated with approbation, and adopted by later systematists, as by Mr. Swainson.

The discovery of the true affinities of the Marsupialia could only flow from an insight into their whole organization, and the question which Mr. Bennett proposes with reference to the genus *Phascolomys*, " What is there of im-

* Annales d'Anatomie et de Physiologie, 1839, p. 237.

portance in the structure of the Wombat, except this solitary character of the Marsupium, to separate it from the Rodent order?"—a question which he might in 1831 have asked with equal force in reference to any other Marsupial genus,—could only be answered satisfactorily by the submission of the Marsupialia in question to a thorough dissection.

Although the Marsupials present modifications of the dental system corresponding with the carnivorous, omnivorous, and herbivorous types, yet they agree with each other, and differ from the analogous Placental Mammalia in having four instead of three true molars, i. e. four molars which are not displaced and succeeded by others in the vertical direction. The incisor teeth, also, either exceed in number those of the analogous Placental classes, or are peculiarly arranged and opposed to each other.

In the locomotive organs it is true that we see some of the Marsupials having a hinder thumb, like the Placental Quadrumana; others are digitigrade, with falculate claws, like the Placental Feræ; a third, as the Wombat, has the feet adapted for burrowing; a fourth, like the Cheironectes, is aquatic, and has webbed feet; yet all these Marsupials agree with each other in having a rotatory movement of the hind foot, analogous to the pronation and supination which, in the placental quadrupeds, are limited when enjoyed at all to the fore feet; and they manifest moreover a peculiar modification of the muscles of the hind leg and foot in relation to these rotatory movements. In those Marsupials, as the Kangaroos, Potoroos, and Perameles, in which the offices of support and locomotion are devolved exclusively or in great part upon the hind legs, these are strengthened at the expense of the loss of the rotatory movements of the feet; but in the enormous development of the two outer toes, and the conversion of the two inner ones into unguiculate appendages, useful only in cleansing the fur, these Marsupials differ from all Placentals, whilst the same peculiar condition of the toes may be traced through the Pedimanous group of Marsupials. Thus the locomotive organs, notwithstanding their adaptation to different kinds of progression, testify to the unity of the Marsupial group in the two remarkable peculiarities of structure above cited.

The vascular system gives evidence to the same effect. We have seen that the Marsupials present the following peculiarities in the structure of the heart: viz. the right auricle manifests no trace of either *fossa ovalis* or *annulus ovalis*, and receives the two *venæ cavæ superiores* by two separate inlets. This generalization is, however, less urgent than the preceding in the present question, because the modification, as regards the separate entry of the superior venæ cavæ, obtains in a few placental species, as in the elephant and certain Rodents; but as the first cited cardiac character is common and peculiar to the Marsupial Mammalia, and as the second, while it is universal in the Marsupials, occurs only as an exceptional condition in the placental series, the arguments which they afford to the unity of the Marsupial group cannot be overlooked in a philosophical consideration of the affinities of the Mammalia.

With respect to the nervous system, it has been shown that in the structure of the brain, the Marsupialia exhibit a close correspondence with the Ovipara in the rudimental state of the *corpus callosum;* the difference which the most closely analogous placental species offer in this respect is broadly marked.

These coincidences in the Marsupialia of important organic modifications of the dental, locomotive, vascular, cerebral, and reproductive systems, establish the fact, that they constitute, with the Monotremes, a natural group inferior on the whole in organization to the Placental Mammalia.

The following is a tabular view* of the subordinate divisions in the Marsupialia regarded as an order of the Implacental sub-class of Mammalia :—

* Of the various forms of Marsupial animals attempted to be arranged in natural groups in the present classification, it may be asked which is the *typical form?* or in other words, which genus combines most of the points of organization peculiarly characterizing the Marsupialia?

We have seen that certain modifications of the nervous, circulating, and generative systems are common to all the genera. But the female generative organs approach nearest to the Rodent type in the small dorsigerous Opossums, in which the characteristic external pouch becomes very nearly obsolete. It is not the genus *Didelphys* therefore that we should select as the type of the Marsupials. It appears to me that there is both a dental and a digital character which may be regarded as eminently marsupial; the former, besides the number of true molar teeth, consists in the opposition of six vertical incisors above to a large procumbent single pair below; the latter is exemplified in the atrophied and coadunate condition of the second and third digits of the hinder foot. The Phalangers, Petaurists, Koalas, Kangaroos, and Potoroos possess, in addition to the ordinary Marsupial characters, both these modifications of teeth and digits. It seems, therefore, that it is from one of these genera that we should select the Marsupial type *par excellence.* If we say the *Phalangers*, it may be objected that the hinder hand and opposable prehensile thumb indicate in these a transition from the Marsupialia to the Quadrumana. Should the *Petauri* be our choice, then again we perceive in the development of the lateral tegumentary folds, and their connection with the locomotive members, a tendency to the Flying Squirrels. The tail-less Koala may be deemed to exhibit in its clumsy form and proportions a resemblance to the tree-bears. The Kangaroos and Potoroos obviously typify the Rodent Jerboas, and they have lost the peculiar rotation of the hind leg and the muscular modification connected therewith. If, however, the type of a natural group of animals, and such I have proved the Marsupial group to be, is that which manifests the greatest number of the structural modifications peculiar to the group, and the smallest number of such as are common to other natural assemblages of Mammalia, then the Koala has the best claim to typical pre-eminence. The Marsupial bones might be readily supposed to afford a simple indication of the most peculiarly Marsupial animal, if they offered different relative magnitudes in different genera: now the range of variety in this respect is, in fact, considerable, and the Marsupial bones present their greatest development in the Koala.

Classification of the Marsupialia.

Tribes.	Families.	Genera.	Sub-genera.
1. Sarcophaga. Three kinds of teeth, canines long in both jaws; a simple stomach, no *intestinum cæcum*	Dasyuridæ ...	Thylacinus. Dasyurus. Phascogale.	
Extinct transitional forms		Phascolotherium. Thylacotherium(?)	Fossil.
2. Entomophaga. Three kinds of teeth in both jaws; a simple stomach, a moderately long *intestinum cæcum*................	Ambulatoria ...	Myrmecobius.	
	Saltatoria......	Chæropus. Perameles.	
	Scansoria	Didelphys	Didelphys. Cheironectes.
3. Carpophaga. Anterior incisors large and long in both jaws; canines inconstant; stomach simple, or with a special gland; a very long *intestinum cæcum*	Phalangistidæ ..	Phalangista	Cuscus. Pseudocheirus. Tapoa.
		Petaurus	Petaurista. Belidia. Acrobata.
	Phascolarctidæ..	Phascolarctus.	
4. Poephaga. Anterior incisors large and long in both jaws; canines present in the upper jaw only, or wanting; a complex stomach, a long *intestinum cæcum*..	Macropodidæ ..	Hypsiprymnus. Macropus.	Lagocheles. Halmaturus. Macropus. Osphranter.
5. Rhizophaga. Two scalpriform incisors in both jaws; no canines; stomach with a special gland; *cæcum* short, wide, with a vermiform appendage	Phascolomyidæ .	Phascolomys.	
		Diprotodon...	Fossil.

MEMBRANE, (in Anatomy,) Gr. μηνιγξ; Lat. *Membrana;* Fr. *Membrane;* Germ. *die Haut.* This term is commonly applied to designate those textures of the body which are disposed or arranged as laminæ, destined to cover organs, to line the interior of cavities, or either singly or by their application one over the other, to constitute the walls of canals or tubes. Expansion with very slight thickness is the main morphological characteristic of membranes in their ordinary sense.

I do not intend here to give any classification of the membranes: the term is extensively used in descriptive as well as in general anatomy; and anatomists differ materially as to the degrees within which they limit its meaning. Anatomists hitherto have been content to adopt the gross anatomy of the textures as the basis of their classification, a circumstance which has given rise to much error, as well as to great variety of opinion. Now, aided as we are by excellent microscopes, and by the light which they have thrown upon the minute anatomy of the tissues, we should only admit that classification which is based on an ultimate or even proximate anatomical analysis. As these points will be all fully treated of in the article Tissue, reference is made to it for the details respecting the membranes.

(R. B. Todd.)

MENINGES.— This word signifies *membranes;* it is specifically applied to those membranous expansions which cover and more or less protect the brain and spinal cord, and in this sense is best interpreted by the German word *Hirnhaut.* The term is in common use on the continent, but not so frequently employed by British anatomists, although always understood by them in the sense above given. It appears to have been thus applied first by Galen, who distinguished μηνιγξ παχυτερη, or the dura mater, and μηνιγξ λεπτη, or the pia mater.

The description of the membranes of the brain and spinal cord will be found in the article Nervous Centres.

(R. B. Todd.)

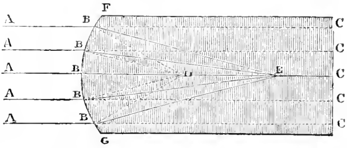
MICROSCOPE, (μικρος, small, and σκοπεω, to look at,) an instrument for aiding the eye in the examination of minute objects. Although a description of the structure and uses of this instrument cannot be considered as strictly belonging to a work like the present, yet the knowledge of them is so closely connected with its general objects that it has been deemed advisable to make it an object of special attention. The applications of this instrument to the purposes of the anatomist and physiologist are so numerous, that a whole treatise might easily be written upon them alone. We are not aware, until we come to think on the subject, how much of our knowledge of what takes place within the living body is dependent upon its revelations. To take a familiar illustration,—the capillary circulation might be, in some degree, guessed at by tracing the ramifications of the bloodvessels as far as they could be discerned with the naked eye; but we should have *known* extremely little of it without the microscope. Our whole knowledge of the early processes of development in plants and animals is gained by the same assistance. Not only is much of that, which ranks as established anatomical or physiological truth, founded upon microscopic researches, but similar researches, which are being prosecuted at the present time, are yielding a harvest of discovery still richer in amount, whilst not less important in its character.

We propose, in the present article, to take a general view of the principles, optical and mechanical, which are concerned in the construction of the microscope; and then to give an outline of the results of some of the most recent enquiries in which it has been profitably employed,—confining ourselves chiefly, however, to those which concern the origin and formation of the principal organized structures. If it be thought that the former portion is too much extended, we have only to say, that we know of no single treatise to which we can refer our readers for a large part of the information which we desire to convey; and that we have therefore judged it desirable to make the article complete in itself.

I. Optical principles governing the construction of microscopes.

All microscopes, except those which operate by reflection (to be hereafter noticed), depend for their operation upon the influence of convex and concave lenses on the course of the rays of light passing through them. This influence is the result of the well-known laws of refraction —that a ray passing from a *rare* into a *dense* medium is refracted *towards* the perpendicular, and vice versâ. When, therefore, a pencil of parallel rays passing through air impinges upon a convex surface of glass, the rays will be made

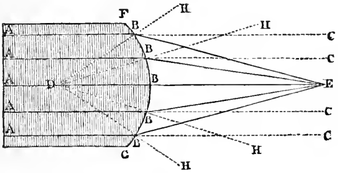
Fig. 144.



A B, parallel rays of light falling upon the convex surface F, B, G; D the centre, D B, D B, radii, which are the perpendiculars to the curved surface at the several points; B C, course of the rays if uninterrupted; B E, their course in consequence of the refraction they have undergone, converging to a focus at E.

to converge, for they will be bent towards the centre of the circle, since the radius is the perpendicular to each point of curvature. The central ray, as it coincides with the perpendicular, will undergo no refraction; the others will be bent from their original course in an increasing degree in proportion as they fall at a distance from the centre of the lens; and the effect upon the whole will be such, that they will be caused to meet at a point, called the *focus*, some distance beyond the centre of curvature. This effect will not be materially changed, by allowing the rays to pass into air again through a *plane* surface of glass, such as would be formed by a section of the glass in the vertical line; a lens of this description is called a *plano-convex* lens; and it will hereafter be shown to possess properties, which render it very useful in the construction of microscopes. But if, instead of passing through a plane surface, the rays re-enter the air through a convex surface, they will be made to converge still more. This may be best understood by considering the course of parallel rays, as in the adjoining

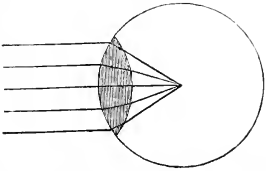
Fig. 145.



A B, parallel rays passing through glass and falling upon the convex surface F B G; B H, B H, radii prolonged, which are the perpendiculars to the curved surface at the several points; B C, course of the rays if unrefracted; B E, their course in consequence of refraction.

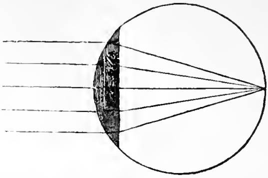
figure (*fig.* 145). Here the radii prolonged will be the perpendiculars to the curved surface; and, according to the law of refraction just alluded to, the rays passing from the dense into the rare medium will be bent *from* the perpendicular, so as to be made to converge towards a focus, as in the former instance. It is easy to see, therefore, that the effect of the second convex surface will be precisely equivalent to that of the first; for the contrary direction of the surface is antagonized by the contrary direction of the refraction; so that the focus of a double convex lens will be at just half the distance from it, or (as commonly expressed) be half the length of the focus of a plano-convex lens. In fact, the focus of the former to parallel rays will be the centre of its sphere of curvature, and its focal length will therefore be the radius; whilst the focus of the latter will be in the opposite side of the sphere, and its focal length will be the diameter. Now it is evident that

Fig. 146.



Parallel rays falling on a double convex lens brought to a focus in its centre; and rays diverging from such a point rendered parallel.

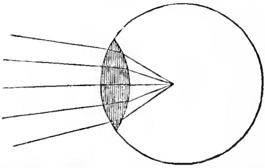
Fig. 147.



Parallel rays falling on a plano-convex lens brought to a focus at the distance of its diameter, and vice versâ.

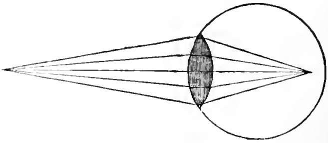
if a double convex lens will bring *parallel* rays to a focus in the centre of its sphere of curvature, it will on the other hand cause rays to assume a parallel direction, which are *diverging* from its focus; so that if a luminous body were placed in that point, all its cone of rays, which fell upon the surface of the lens, would pass out in a cylindrical form. Again, if rays already *converging* fall upon a convex lens, they

Fig. 148.



Rays already converging brought to a focus nearer than the centre; and rays diverging from such a point, still diverging in a diminished degree.

Fig. 149.

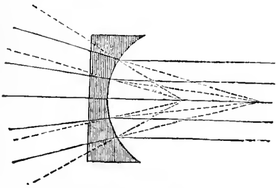


Rays diverging from points more distant than the principal focus on either side brought to a focus beyond it.

will be brought to a focus at a point nearer to it than the focus for parallel rays (which is called its principal focus); and, if they be diverging from a distant point, their focus will be more distant than the principal focus. The further be the point from which they diverge, the more nearly will the rays approach the parallel direction; until, at length, when the objects are very distant, their rays in effect become parallel, and are brought to a focus in the centre of the sphere. If they diverge from the other extremity of the diameter of the sphere, they will be brought to a focus at a corresponding distance on the other side of the lens. On the other hand, if they be diverging from a point *within* the principal focus, they will neither be brought to converge nor be rendered parallel, but will diverge in a diminished degree. The same principles apply equally to a plano-convex lens, the distance of its principal focus being understood to be the *diameter* of the sphere. They also apply to a lens whose surfaces have different curvatures; the principal focus of such a lens is found by multiplying the radius of one surface by the radius of the other, and dividing this product by half the sum of the same radii. For the rules by which the foci of convex lenses may be found for rays of different degrees of convergence and divergence, we must refer to works on optics.

The influence of *concave* lenses will evidently

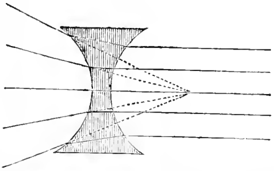
Fig. 150.



Parallel rays falling on a plano-concave lens made to diverge as from its principal focus, and rays converging to that focus rendered parallel.

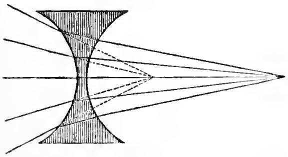
be precisely the converse of that of convex. Rays which fall upon them in a parallel direction will be made to *diverge* as if from the principal focus, which is here called the *negative* focus. This will be, for a plano-concave

Fig. 151.



Parallel rays made to diverge as from the principal focus, and rays converging to that focus rendered parallel.

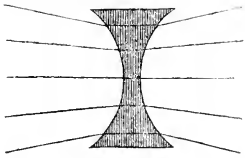
Fig. 152.



Rays greatly converging made to converge less, and rays slightly diverging made to diverge more.

lens, at the distance of the diameter of the sphere of curvature; and for a double concave, in the centre of that sphere. In the same manner, rays which are converging to such a degree that,

Fig. 153.



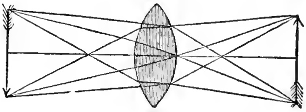
Rays slightly converging made to diverge.

if uninterrupted, they would have met in the principal focus, will be rendered parallel; if converging more, they will still meet, but at a greater distance; and if converging less, they will diverge as from a negative focus at a greater distance than that for parallel rays. If already diverging, they will diverge still more, as from a negative focus nearer than the principal focus; but this will approach the principal focus, in proportion as the distance of the point of divergence is such, that the direction of the rays approaches the parallel.

If a lens be convex on one side and concave on the other, forming what is called a *meniscus*, its effect will depend upon the proportion between the two curvatures. If they are equal, as in a watch-glass, no perceptible effect will be produced; if the convex curvature be the greater, the effect will be that of a less powerful *convex* lens; and if the concave curvature be the more considerable, it will be that of a less powerful *concave* lens. The focus of convergence for parallel rays in the first case, and of divergence in the second, may be found by dividing the product of the two radii by half their difference.

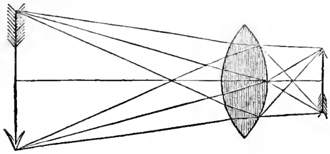
Hitherto we have considered only the effects of lenses upon a pencil of rays issuing from a single luminous point, and that point situated in the line of its axis. If the point be situated above the line of its axis, the focus will be below it, and vice versâ. The surface of every luminous body may be regarded as comprehending an infinite number of such points, from every one of which a pencil of rays proceeds, and is refracted according to the laws already specified; so that a perfect but inverted image or picture of the object is formed upon any surface placed in the focus, and adapted to receive the rays.

Fig. 154.



In optical diagrams it is usual, in order to avoid confusion, to mark out the course of the rays proceeding from two or three only of such points. By an inspection of the subjoined figures, it will be evident that, if the object be placed at twice the distance of the principal focus, the image being formed at an equal dis-

Fig. 155.

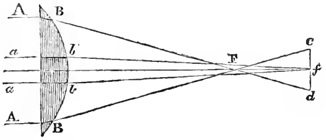


Formation of images by convex lenses.

tance on the other side of the lens, will be of the same dimensions with the object: whilst, on the other hand, if the object be nearer the lens, the image will be farther from it, and of larger dimensions; and if the object be farther from the lens, the image will be nearer to it, and smaller than itself. Further, it is to be remarked, that the larger the image in proportion to the object, the less bright it will be, because the same amount of light has to be spread over a greater surface; whilst a smaller image will be much more brilliant, in the same proportion.

The knowledge of these general facts will enable us readily to understand the ordinary operation of the microscope; but the instrument is subject to imperfections of various kinds, the mode of remedying which cannot be comprehended without an acquaintance with their nature. One of these imperfections results from the *spherical aberration* of the rays which have passed through lenses, whose curvatures are equal over their whole surfaces. If the course of the rays be carefully laid down, it will be found that they *do not all meet exactly*

Fig. 156.



A B, rays falling on the periphery of the lens; F, focus of these; *a*, *b*, rays falling nearer the centre; *f*, more distant focus of these.

in the foci already stated, but that the focus of the rays which have passed through the peripheral portion of the lens is much closer to it than that of the rays which are nearer the line of its axis; so that, if a screen be held in the former, the rays which have passed through the central portion of the lens will be stopped by it before they have come to a focus; and if the screen be carried back into the focus of these, the rays which were most distant from the axis will have previously met and crossed, so that they will come to it in a state of divergence. In either case, therefore, the image will have a certain degree of indistinctness; and there is no one point to which all the rays can be brought by a lens of spherical curvature. The difference between the focal points of the central and of the peripheral rays is termed the *spherical aberration*. It is obvious that, to produce the desired effect, the curvature is required to be increased around the centre of the lens, so as to bring the rays which pass through it more speedily to a focus, and to be diminished towards the circumference, so as to throw the focus of the rays influenced by it to a greater distance. The requisite conditions may be exactly fulfilled by a lens one of whose surfaces, instead of being spherical, is a portion of an ellipsoid or hyperboloid of certain proportions; but the difficulties in the way of the mechanical execution of lenses of this description are such, that, for all practical purposes, they have been entirely abandoned in favour of lenses with spherical surfaces. Various means have been devised for diminishing the aberration of these. In microscopes of ordinary construction, the method employed is to diminish the aperture or working surface of the lens, so as to employ only the rays that pass through the central part, which, if sufficiently small in proportion to the whole sphere, will bring them all to nearly the same focus. The use of this may be particularly noticed in the object-glasses of common microscopes; where, although the lens itself be large, the greater portion of its surface is rendered inoperative by a *stop*, which is a plate with a circular aperture interposed between the lens and the rest of the instrument. If this aperture be gradually enlarged, it will be seen that, although the image becomes more and more illuminated, it is at the same time becoming more and more indistinct; and that, in order to gain *defining power*, the aperture must be reduced again. Now this reduction is attended with two great inconveniences; in the first place, the loss of intensity of light, the degree of which will depend upon the quantity transmitted by the lens, and will vary therefore with its aperture; and, secondly, the diminution of the number or quantity of rays, which will prevent the surfaces of objects from being properly seen. Thus, for example, we shall suppose the observer to be looking at the scales of a butterfly's wing with a microscope furnished with two object-glasses of the same focal length,—one corrected, the other not so. If, with the same illumination of the object, he apply to it the uncorrected objective, the aperture of which is necessarily small, after having looked at it with the corrected lens, he will, in the first place, perceive that the whole field is much darker; but if, by increasing his illumination, he give the image an equal brightness, and see its outline with equal distinctness, he will be completely unable to see with the uncorrected lens a series of delicate lines upon the surface of the scale, which the other makes evident. The power of exhibiting these and similar objects is termed *penetration;* it depends upon the size of the conical pencils of light admitted by the lens, and therefore upon its aperture.

The spherical aberration may be considerably diminished by making the most advantageous use of *single* lenses. Thus the aberration of a plano-convex lens, whose convex side is turned towards parallel rays, is only $\frac{17}{100}$ths of its thickness, whilst, if the plane side be turned towards the object, the aberration is $4\frac{1}{2}$ times the thickness of the lens. Hence, when a plano-convex lens is employed, its convex surface should be turned towards a distant object, when it is used to form an image by bringing to a focus parallel or slightly-diverging rays; but it should be turned towards the eye, when it is used to render parallel the rays which are diverging from a very near object. The single lens having the least spherical aberration is a double convex, whose radii are as 1 to 6. When the flattest face is turned toward parallel rays, the aberration is nearly $3\frac{1}{2}$ times its thickness; but when the most convex side receives or transmits them, the aberration is only $\frac{7}{120}$ths of its thickness. The spherical aberration may be still further diminished, however, or even got rid of altogether, by making use of combinations of lenses so disposed that their opposite aberrations shall correct each other, whilst magnifying power is still gained. For it is easily seen that, as the aberration of a concave lens is just the opposite of that of a convex lens, the aberration of a convex lens placed in its most favourable position may be corrected by a concave lens of much less power in its most unfavourable position; so that, although the power of the convex lens is weakened, all the rays which pass through this combination will be brought to one focus. This is the principle of the *aplanatic doublet* proposed by Sir J. F.W. Herschel, consisting of a double-convex lens of the most favourable form, and a meniscus with the concave of longer focus than the convex.* A doublet of this kind may be made of great use in the microscope, as we shall hereafter show.

Fig. 157.

Herschel's doublet.

But the spherical aberration is not the only imperfection with which the optician has to contend in the construction of microscopes. A difficulty equally serious arises from the unequal refrangibility of the different coloured rays, which together make up white or colourless light,† so that they are not all brought to the same focus, even by a lens free from spherical aberration. It is this difference in their refrangibility which causes their complete separation by the prism into a spectrum; and it manifests itself, though in a less degree, in the image formed by a convex lens. For if parallel rays of white light fall upon a convex surface, the most refrangible of its component rays, namely, the *violet*, will be brought to a focus at a point somewhat nearer to the lens than the principal focus, which is the mean of the whole; and the converse will be true of the *red* rays, which are the least refrangible, and whose focus will therefore be more distant.

* The exact curvatures to be given to these surfaces will be found in the original memoir, Phil. Trans. 1821.

† It has been deemed better to adhere to the ordinary phraseology, when speaking of this fact, as more generally intelligible than the language in which it might be more scientifically described, and at the same time leading to no practical error.

Fig. 158.

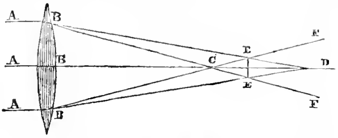


Diagram illustrative of chromatic aberration.

A B, rays of white light refracted by a convex lens; C, the focus of the violet rays, which then cross and diverge towards E F; D, the focus of the red rays which are crossed at the points E E, by the violet; the middle point of this line is the mean focus, or focus of least aberration.

This is easily proved experimentally. If a lens be so fixed as to receive the solar rays, and to illuminate a white screen at any distance between the lens and the mean focus, the luminous circle will have a red border, because the red rays will there form the exterior of the cone; but if it be removed beyond the mean focus, the circle will have a violet border, because the violet rays will then be outermost. As the spherical aberration would be mixed up with the chromatic in such an experiment, the undisguised effect of the latter will be better seen by taking a large convex lens, and covering up its central part, so as to allow the light to pass only through a peripheral ring; and since the greater the alteration in the course of the rays, the greater will be the separation of the colours, (or *dispersion*, as it is technically called,) this ring will exhibit the phenomenon much better than would be done by the central portion of the lens. Hence, in practice, the chromatic aberration is partly obviated by the same means used to diminish the spherical aberration,—the contraction of the aperture of the lens, so that a very small portion of the whole sphere is really employed. But this contraction is attended with so much injury to the performance of the microscope in other respects, that it becomes extremely desirable to avoid it. In no single lens can any correction for chromatic aberration be effected; and it requires a very nice adjustment of two, three, or even more, to accomplish this with perfection.

The correction is accomplished by bringing into use the different dispersive powers of various materials, which bear no relation to their simple refracting power. As the effects of concave lenses are in all respects the converse of convex, it is obvious that, if a concave lens of the same curvature be placed in apposition with the convex, in such an experiment as that just alluded to, the dispersion of the rays will be entirely prevented, but neither will any change in the course of the rays take place. If, however, we can obtain a substance of higher dispersive power in proportion to its power of refraction, it is obvious that a concave lens of less curvature formed of it will correct the *dispersion* occasioned by the convex lens, without altogether antagonising the *refraction* of the latter. This is accomplished without any essential difficulty in practice; for the dispersive power of flint-glass is so much greater than that of crown-glass, that a convex lens of the former, the focal length of which is 7⅗ inches, will produce the same degree of colour with a convex lens of crown-glass whose focal length is 4⅓ inches. Hence a concave lens of the former material and curvature will fully correct the dispersion of a convex lens of the latter, and will yet diminish its refractive power only to such an extent as to make its focus ten inches. The correction for chromatic aberration in such a lens would be perfect, if it were not that, although the extreme rays, violet and red, are thus brought to the same focus, the dispersion of the rest is not equally compensated; so that what is termed a *secondary spectrum* is produced, the images of objects seen through such a lens being bordered on one side with a purple fringe, and on the other with a green fringe. Moreover such a lens is not corrected for spherical aberration; and it must of course be rendered free from this, to be of any service, however complete may be its freedom from colour.

Opticians have long since been able to effect the required corrections, with sufficient accuracy for most practical purposes, in the construction of large object glasses for telescopes; the size of which has been only limited by the impossibility of obtaining glasses of large dimensions perfectly free from faults. But it has been only of late years, that the construction of achromatic and aplanatic object-glasses for microscropes has been considered practicable,—their extremely minute size appearing to forbid the employment of the necessary combinations, since a very high amount of accuracy is required in the several curvatures, in order to obtain any real improvement. About the year 1820, however, the attempt was first made in France by M. Selligues, who was followed by Frauenhofer at Munich, by Amici at Modena, and by Mr. Tulley of London; and with these attempts a new era in the history of the microscope may be said with truth to have commenced. The work has been prosecuted, both theoretically and practically, with the greatest zeal, and the result has been most successful. By combining two or three groups of double lenses, each corrected in a particular manner, so that the whole is quite free from aberration, a perfectly sharp and clearly-defined image may now be obtained through a lens of many times the aperture of those formerly in use; and the differences in the representation of the objects under enquiry, between such lenses and a good achromatic, are such as could not have been, *à priori*, suspected. One of the most pleasing results of this improvement has been the greatly-increased unanimity amongst microscopical observers, as to the appearances actually witnessed by them; for with the old and imperfect instruments, great uncertainty could not but exist in regard to many objects, of whose nature every one formed his own opinion, frequently according to preconceived ideas; but at present the objects are presented to the sight of each observer possessed of a good instrument, with so much more clear and uniform an appearance, that there is much less scope for the play of his imagination as to their real character,—however much he may exercise it upon their history. It would be foreign to the purpose of this article to enter into scientific details upon the minutiæ of the construction of achromatic combinations; but it may not be amiss to state that, in the opinion of the author, English artists have far surpassed foreigners in the construction of lenses of very short focus, whilst some foreign combinations which he has seen, of low magnifying power, possess an advantage over those of British make,—the constructors of the latter having sometimes sacrificed what he deems adequate correctness in aiming at a very large aperture.*

With these preliminary details as to the nature of the means by which microscopic power is obtained, we shall proceed to notice their chief applications to practice. Excluding for the present the solar and gas microscopes, in which an image visible to any number of persons at once is formed upon a screen, and is viewed by them precisely as other surrounding objects would be, we shall consider the instruments (to which the term microscope is more commonly applied), whose effects are produced by their influence on the rays of light which enter the eye of the observer, and which can be used, therefore, by but one at the same time. These are distinguished as *single* or *simple*, and *compound* microscopes. Each of these kinds has its peculiar advantages for the anatomist; and we shall, therefore, describe the construction and uses of both in some detail. Their essential difference consists in this,—that in the former the rays of light which enter the eye of the observer proceed directly from the object itself, after having been subject only to a change in their course, whilst in the latter an inverted image of the object is formed by a lens, which image is viewed by the observer through a simple microscope, as if it were the object itself. The *simple* microscope *may* consist of *one* lens, but (as will be presently shown) it may be formed of *two* or *even* three; but these are so disposed as to produce an action upon the rays of light correspondent to that of a single lens. For this kind of microscope, therefore, we prefer the term *simple* to single. In the compound microscope, on the other hand, not less than two lenses must be employed, one to form the inverted image of the object, and this being nearest to it is called the *object-glass*, whilst the other magnifies that image, being interposed between it and the eye of the observer, and is hence called the *eye-glass:* Both these may be constructed of several lenses, as will be hereafter shown; but they are so arranged as to have the functions of a single lens, and are only combined

* Those who wish to study the principles which now guide opticians in their construction, should refer to Mr. J. J. Lister's paper in the Phil. Trans. for 1829, and Mr. Ross's Memoir in the Trans. of the Society of Arts, vol. ii.

for the purpose of correcting the defects incidental to it.

In order to gain a clear notion of the mode in which a single lens serves to magnify minute objects, it is necessary to revert to the phenomena of ordinary vision. An eye free from any defect has a considerable power of adjusting itself in such a manner as to gain a distinct view of objects placed at extremely varying distances; but the image formed upon the retina will of course vary in size with the distance of the object; and the amount of detail perceptible in it will follow the same proportion. To ordinary eyes, however, there is a limit within which no distinct image can be formed, on account of the too great divergence of the rays of the different pencils which then enter the eye; since the eye is usually adapted to receive and bring to a focus rays which are parallel or slightly divergent. This limit is variously stated at from five to ten inches; we are inclined to think from our own observations, that the latter estimate is nearest the truth; that is, although a person with ordinary vision may see an object much nearer to his eye, he will see little if any more of its details, since what is gained in size will be lost in distinctness. Now the utility of a convex lens interposed between a near object and the eye consists in its reducing the divergence of the rays forming the several pencils which issue from it; so that they enter the eye in a state of moderate divergence, as if they had issued from an object beyond the nearest limit of distinct vision; and a well-defined picture is consequently formed upon the retina. But not only is the course of the several rays in

Fig. 159.

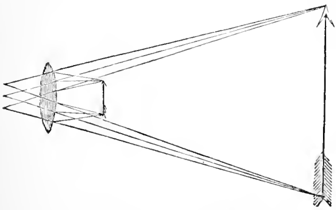

Diagram illustrating the use of the Simple Microscope.

each pencil altered as regards the rest by this refracting process, but the course of the pencils themselves is changed, so that they enter the eye under an angle correspondent with that at which they would have arrived from a much larger object situated at a greater distance. The picture formed upon the retina, therefore, corresponds in all respects with one which would have been made by the same object, greatly increased in its dimensions, and viewed at the smallest ordinary distance of distinct vision. A short-sighted person, however, who can see objects distinctly at a distance of three or four inches, has the same power in his eye alone, by reason of its greater convexity, as that which the person of ordinary vision gains by the assistance of a convex lens which shall enable him to see at the same distance with equal distinctness. It is evident, therefore, that the magnifying power of a single lens, depending as it does upon the proportion between the distance at which it renders the object visible, and the nearest distance of unaided distinct vision, must be different to different eyes. It is ordinarily estimated, however, by finding how many times the focal length of the lens is contained in ten inches; since, in order to render the rays from the object nearly parallel, it must be placed very nearly in the focus of the lens; and the picture is referred by the mind to an object at ten inches distance. Thus, if the focal length of a lens be one inch, its magnifying power for each dimension will be ten times, and consequently a hundred superficial; if its focal distance be only one-tenth of an inch, its magnifying power will be a hundred linear or ten thousand superficial. The use of the convex lens has the further advantage of bringing to the eye a much greater amount of light than would have entered the pupil from the enlarged object at the ordinary distance, provided its own diameter be greater than that of the pupil. It is obviously necessary, especially when lenses of very high magnifying power are being employed, that their aperture should be as large as possible; since the light issuing from a minute object has then to be diffused over a large picture, and will be proportionally diminished in intensity. But the shorter the focus the less must be the diameter of the sphere of which the lens forms a part; and unless the aperture be proportionally diminished, the spherical and chromatic aberrations will interfere so much with the distinctness of the picture, that the advantages which might be anticipated from the use of such lenses will be almost negatived. Nevertheless, the simple microscope has always been an instrument of extreme value in anatomical research, owing to its freedom from those errors to which, as will hereafter appear, the compound microscope is subject; and the greater certainty of its indications is evident at once from the fact, that the eye of the observer receives the rays sent forth by the object itself, instead of those which proceed from an image of that object. A detail of the means employed by different individuals, for procuring lenses of extremely short focus, though possessing much interest in itself, would be misplaced here; since recent improvements, as will presently be shown, have superseded the necessity of all these. It may, however, be stated that Leeuwenhoeck, De la Torre, and others among the older microscopists, made great use of small globules procured by fusion of threads or particles of glass. The most important suggestion for the improvement of the simple microscope composed of a single lens proceeded some years ago from Dr. Brewster, who proposed to substitute diamond, sapphire, garnet, and other precious stones of high refractive power, for glass, as the material of single lenses. A lens of much longer radius of curvature might thus be employed to gain an equal magnifying power, and the aperture would admit of great extension without a proportional increase in the spherical and chromatic aberrations. This suggestion has been carried into practice with complete success as regards the performance of lenses executed on this plan; but the difficulties of various kinds in the way of their execution are such as to render them very expensive; and as they are not superior to the combination now to be described, they have latterly been quite superseded by it.

This combination was first proposed by Dr. Wollaston, and is known as his doublet. It consists of two plano-convex lenses, whose focal lengths are in the proportion of one to three, or nearly so, having their convex sides directed towards the eye, and the lens of shortest focal length nearest the object. In Dr. Wollaston's original combination no stop was interposed, and the distance between the lenses was left to be determined by experiment in each case. A great improvement was subsequently made, however, by the introduction of a stop between the lenses, and by the division of the power of the smaller lens between two; this is due to Mr. Holland.* By these means a combination may be produced, in which the errors are made to correct each other so nearly that all the advantages of a wide aperture with a very short focus may be gained. The general nature of the performance of a doublet or triplet may be understood from the adjoining figure, (*fig.* 160,) in which L O L′ is

Fig. 160.

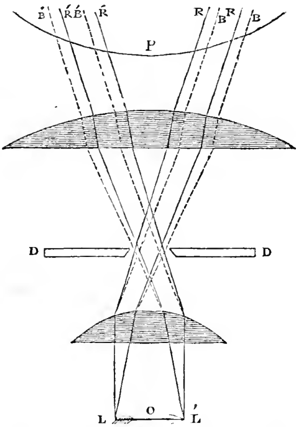

Diagram of the passage of rays through a doublet.

the object, P a portion of the pupil, and D D the stop. The pencils of light from the two extremities, L L′, of the object cross each other in the stop, and consequently pass through the two lenses on the opposite sides of the axis O P; so that each becomes affected by opposite errors, which to a certain extent balance and correct one another. To take the pencil L, for instance, which enters the eye at R B, R B; it is bent to the right at the first lens, and to the left at the second; and as each refraction alters the direction of the blue rays more than of the red, and moreover, as the blue rays fall nearer the margin of the second lens, where the increased power of the refraction, consequent upon the distance from the centre, compensates in some degree for the greater focal length of the second lens, the blue and red rays will emerge very nearly parallel, and are therefore colourless to the eye. At the same time the spherical aberration has been diminished by the circumstance that the side of the pencil, which passes one lens nearest the axis, passes the other nearest the margin. This explanation applies only, however, to the pencils near the extremities of the object. The central pencil, it is obvious, will pass through the same relative portions of the two lenses, and only an imperfect correction will therefore take place, and of those issuing from the intermediate points the amount of correction will vary with their proximity to the centre or to the circumference. Hence a doublet is not a *perfect* magnifier; but it is very much superior to a single lens, and may be so constructed as to show many of the usual test-objects,—especially those in which a moderate amount of *penetration* is sufficient, provided the *definition* be good,—in a very beautiful manner. Its *angle of aperture*, however, by which is meant the angle of the apex of the conical pencils of rays admitted by it, cannot be advantageously increased much beyond 40° or 45°. But when the smaller lens is replaced by a combination of two others, so as to form a triplet, their joint aberration is so much less

Fig. 161.

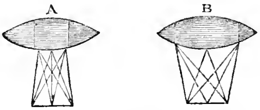

Diagram to illustrate angle of aperture.

A, lens with small opening, admitting only pencils of rays diverging at an angle of 15°; B, lens with large opening, admitting pencils of 50°.

that it is more counterbalanced by the third lens placed above the stop. In this manner the transmission of a still larger angular pencil, —even to 65°,—is rendered compatible with distinctness; and great penetrating power is thus combined with perfect definition, as well as with brilliancy of illumination. For the purposes of anatomical investigation, as we shall hereafter state, we consider good doublets and triplets, where circumstances admit of their employment, superior to any other kind of magnifying instrument. The principal disadvantages which the use of them involves are the close proximity to the object required by their very short focus when a high

* Trans. of Soc. of Arts, vol. xlix.

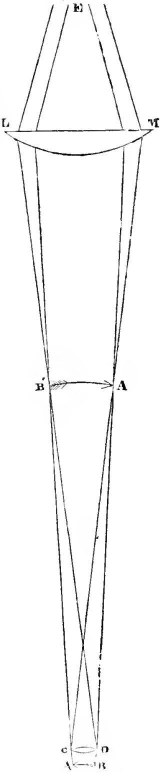
magnifying power is employed; and the straining of the eye, which is occasioned by their very minute aperture. Thus a triplet in our possession, which will show the most difficult test-objects, has a focal distance of only about $\frac{1}{35}$th of an inch, and an aperture through which the smallest pin would scarcely pass. But the first of these disadvantages is more apparent than real. The object should be always covered with talc, (which may be easily split into laminæ of the $\frac{1}{300}$th of an inch in thickness,) for the purpose of protecting both it and the lens from injury by accidental contact; and the magnifier should not be screwed into the arm which carries it, but loosely fitted, so that, if the observer should happen to bring the arm too near the stage, he may not force down his lens upon the object. As Mr. Holland justly observes, " Should the proximity of the object to the lowest lens of the triplet be urged as a material objection to its usefulness, it may be answered that the whole microscope is a mass of delicacies; consequently, it cannot be allowed that a line be arbitrarily drawn, beyond which every thing is to be considered as too delicate." The second of the above objections must be obviated by never continuing the use of deep powers in a simple microscope for any length of time at one sitting, and by taking care to adjust the instrument in such a manner that the head may be as little inclined forwards as possible.

The only other form of simple microscope which we shall notice is one commonly known under the name of the Coddington lens. The first idea of it was given by Dr. Wollaston, who proposed to cement together two plano-convex, or hemispherical lenses, by their plane sides, with a stop interposed, the central aperture of which should be equal to $\frac{1}{5}$th of the focal length. The great advantage of such a lens is that the oblique pencils pass, like the central ones, at right angles with the surface; and that they are consequently but little subject to aberration. The idea was further improved upon by Mr. Coddington, who pointed out that the same end would be much better answered by taking a sphere of glass, and grinding away the equatorial parts, the groove being then filled with opaque matter, so as to limit the central aperture. Such a lens gives a large sphere of view, admits a considerable amount of light, and is equally good in all directions; but its powers of definition are by no means equal to those of an achromatic lens, or even of a doublet. This form is very useful, therefore, as a hand lens, in which a high power is not required, but has no particular advantages for magnifiers of short focus, nor for the object-glasses of a compound microscope.*

It may be desirable to mention that a magnifier, now known under the name of the Stanhope lens, and much praised by those interested in its sale, is nothing more than a double convex glass, much thicker than ordinary, so that an object in contact with one of its surfaces shall be in focus to the eye placed behind the other. This is an easy method of applying rather a high magnifying power to scales of butterflies' wings and other similar flat and minute objects; but the instrument is totally destitute of value as a means of scientific research, and must be regarded as an ingenious philosophical toy.

Compound Microscope. — The compound microscope essentially consists, as already stated, of two lenses, which are so disposed that one of them receives the rays of light from the object, and forms an image by its refraction of them; and this image is seen by the eye through the second lens, which acts upon it as a simple microscope. The principle of such a microscope will be at once understood from the adjoining diagram (*fig.* 162). According to the laws already stated, if the object be at a less distance from the lens than its diameter of curvature (supposing it to be a double-convex lens, or twice that distance of a plano-convex) the image will be larger than the object; and this in proportion as the latter is brought nearer to the principal focus, at which it can give rise to no image, as its rays after refraction become parallel. Hence, by the use of the same object-glass, a considerable variety of power might be obtained; for, if the image be formed near the lens, it will be small; but if the object be caused to approach it, the image will be thrown to a considerable distance, and will be proportionably magnified. The eye-piece would of course require, however, a corresponding re-adjustment; and, in fact, the construction of the whole instrument would need modifica-

Fig. 162.



A B, the object, of which an amplified image is formed by the object-glass C D, in the contrary direction, at A′ B′, by the convergence of the rays of the several pencils to a focus. These again diverging are received by the eye-glass L M, which gives them the nearly parallel direction necessary for them to enter the eye, and causes the apparent size of the image to be E.

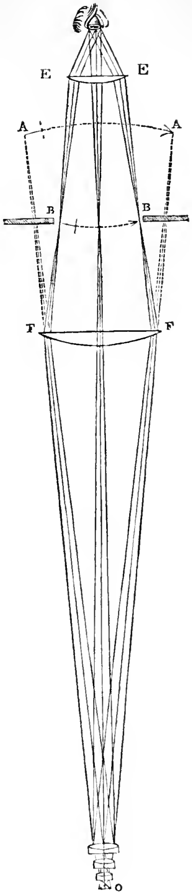
* We think it right to state that many of the magnifiers sold as Coddington lenses are not really (as we have satisfied ourselves) portions of spheres, but are manufactured out of ordinary double-convex lenses, and will be destitute, therefore, of many of the above advantages.

tion Further, the optical disadvantages of such a plan would be considerable, for the nearer to the principal focus of the lens the object is brought, the more obliquely will the rays fall upon its surface, and the greater, therefore, will be the errors of aberration. This method of augmenting the power of a microscope has been adopted in spite of these disadvantages,* but it is not found to answer. Nevertheless, it is capable of being made of great utility, as we shall presently show, to a limited extent. A much more generally convenient method of varying the power of the microscope is to employ, as object-glasses, lenses of different foci; and thus, as the same distance between the image and the lens is constantly maintained, whilst that of the object varies, the number of times that the latter is amplified is changed in a like proportion. In whatever mode additional amplification be obtained, two things must always result from the change; the portion of the surface of the object, of which an image can be formed, must be diminished, and the quantity of light spread over that image must be proportionably lessened. In the use of high magnifying powers, the compound microscope has the great advantage over the simple, that the object need not be brought to nearly the same proximity with the lens, and that much more of it can be seen with comfort at a time. The long focus and large aperture with which the eye-piece is usually made prevent even the prolonged use of the instrument from acting prejudicially on the visual powers, except in cases of peculiar tendency to nervous disorders of the eye. And as the power of the eye-piece as well as that of the object-glass can be raised, there are scarcely any limits to the magnifying power that *may be* obtained. Practically, however, there are limits, arising from the fact that, as the amplification is greater, the aberrations will be increased in even an augmented proportion; so that these completely antagonise the benefit otherwise derivable from the employment of high powers. The aberrations can only be diminished by contracting the aperture of the object-glass; and this renders the image so dark that no real advantage is gained. Moreover, the imperfections necessary to the best compound microscope, in which ordinary lenses are employed, are further augmented by the slightest error in the centering of the lenses, so that their axes do not coincide.

In addition to the two lenses of which the compound microscope has been stated essentially to consist, another is usually introduced between the object-glass and the image formed by it. The ordinary purpose of this lens is to change the course of the rays in such a manner that the image may be formed of dimensions not too great for the whole of it to come within the range of the eye-piece, and consequently to allow more of the object to be seen at once.

* We have seen a microscope, constructed by Chevalier, in which the tube was capable of being drawn out to the length of between three and four feet!

Fig. 163.



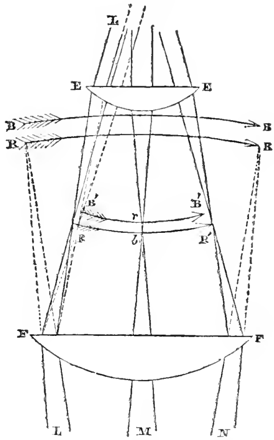
Section of Compound Microscope, with field-glass introduced.

A A, the image which would be formed by the object-glass alone; B B, the image formed by the interposition of the field-glass F F; the *whole* of this image is within the range of vision of the eye-glass E E, and the field of view is therefore increased.

Hence it is called the *field-glass* (*fig.* 163). It may be so adjusted, however, in regard to the eye-glass, as to correct its errors in almost a perfect degree; and it is now, therefore, usually considered as belonging to the ocular end of the instrument,—the *eye-glass* and the *field-lens* being together termed the *eye-piece*. Various forms of this eye-piece have been proposed by different opticians, and one or other will be preferred, according to the purpose for which it be required. It may be laid down as a general principle, however, that to give the highest effect to the microscope, in regard to clearness of view and penetrating power, no more than *two* lenses should be employed; and that when a certain amount of these may be sacrificed to gain a large flat field, *three* is the largest number which can be introduced with any benefit. This principle is founded on the fact that, whenever light impinges on the surface of even the most transparent body, a part of it only is transmitted, the remainder being reflected. In the passage of light through ordinary lenses, therefore, a certain quantity is lost by reflection at each surface; and every multiplication in the number of lenses entails, therefore, a positive evil, which may or may not be counterbalanced by the good it effects. In the doublet or triplet already described, the correction of the aberrations is an advantage much greater than the injury resulting from the substitution of four or six surfaces for two; but this is by no means the case in the eye-piece, in which (from their low power) the aberrations are much less. Hence, when too many lenses are employed in it, although the field of view (that is, the circle within which the image is comprehended) may be very much enlarged and rendered flatter, the brilliancy and sharpness of the image are so much impaired, and it is invested with so much false colour, that, for all scientific purposes, the instrument is rather deteriorated than improved.

The eye-piece which may be most advantageously employed with achromatic object-glasses, to the performance of which it is desired to give the greatest possible effect in regard to defining and penetrating power, without the necessity of a large field, is that termed the Huyghenian, having been employed by Huyghens for his telescopes, although without the knowledge of all the advantages which its best construction rendered it capable of affording. It consists of two plano-convex lenses with their plane sides towards the eye. These are placed at a distance equal to half the sum of their focal lengths; or, to speak with more precision, at half the sum of the focal length of the eye-glass, and of the distance from the field-glass at which an image of the object-glass would be formed by it. A stop or diaphragm must be placed half-way between the two lenses. By Huyghens this arrangement was intended merely to diminish the spherical aberration; but it was subsequently shown by Boscovich that the chromatic dispersion was also in great part corrected by it. Since the introduction of achromatic object-glasses for compound microscopes, it has been further shown that all error may be avoided by a slight over-correction of these, so that the blue and red rays may be caused to enter the eye in a parallel direction, and thus to produce a colourless image, though not actually coincident (*fig.* 164). Further, the image produced by the meeting of the rays after passing through the field-glass is by it rendered convex towards the eye-glass, instead of concave, so that every part of it may be in focus at the same time, and the field of view thereby rendered flat. Those who desire to gain more information upon this subject than they can from the accompanying diagram and the explanation of it, may be referred to Mr. Varley's investigation of the properties of the Huyghenian eye-piece in the 51st volume of the Transactions of the Society of Arts, and to the article "Microscope" in the Penny Cyclopædia.

Fig. 164.



Section of Huyghenian eye-piece, adapted to over-corrected achromatics.

L M N, the two extreme rays of three pencils, which, without the field-glass, would form a blue image convex to the eye-glass at B B, and a red one at R R. By the field-glass, however, a blue image, concave to the eye-glass, is formed at B′ B′, and a red one at R′ R′. As the focus of the eye-glass is shorter for blue rays than for red rays, by just the difference in the place of these images, their rays, after refraction by it, enter the eye in a parallel direction, and produce a picture free from false colour. If the object-glass had been rendered perfectly achromatic, the blue rays, after passing the field-glass, would have been brought to a focus at *b*, and the red at *r*, so that an error would be produced, which would have been increased instead of antagonised by the eye-glass.

By an achromatic object-glass for a compound microscope, therefore, is not meant one which simply contains within itself a perfect correction for its own errors, but one in which the usual order of dispersion is so far reversed that the light, after undergoing the series of changes effected by the eye-piece, shall come uncoloured to the eye. "We can give no specific rules," says the writer of the article just referred to, whom we believe to have had great practical experience in the matter, "for producing these results. Close study of the formulæ for achromatism given by celebrated mathematicians will do much; but the principles must be brought to the test of repeated experiment. Nor will the experiments be worth any thing, unless the curves be most accurately measured and worked, and the lenses centred and adjusted with a degree of precision which, to those who are familiar only with telescopes, will be quite unprecedented." We are not favourable to the use of a very high magnifying power in the eye-piece; and we believe that it will be discontinued in proportion to the perfection attained in object-glasses. We have seen microscopes of foreign construction in which only object-glasses of comparatively long focus were employed, and the required power was made up by the great convexity in the eye-glass; but the performance of these was not to be compared to that of instruments of British manufacture. Our own experience leads us to think that there are very few objects of which more can be made out with a deep than with a shallow eye-piece,—the diminution in distinctness and loss of sight being nearly sufficient to counterbalance the gain derived from increased power. Hence the *magnifying power* of an instrument is by no means to be regarded as an indication of its excellence; for that is to be considered as the best which, *ceteris paribus*, will show the most with the lowest power. It may be scarcely an exaggeration to affirm that there are few objects of which the details may not be as well made out by an achromatic microscope magnifying but 100 diameters, as by the best ordinary microscope magnifying 1000; and there are many objects shown with the greatest readiness by the former, which are totally inscrutable by the latter.

Next in order of optical perfection to the achromatic microscope with the Huyghenian eye-piece, we are disposed to rank the doublet microscope, invented by Mr. Holland. This gentleman has proposed to adapt to his doublets and triplets a compound body, containing an eye-piece somewhat resembling the Huyghenian, but differing from it in having the lenses fixed at a distance equal to the whole sum of their foci. "By this increase of distance, light and defining power are gained, although the magnifying power and the field of view are diminished; but at the same time the latter is rendered very perfect." Having ourselves had a microscope constructed upon this principle, we can speak in very high terms of its performance. The field of view will appear *very* small to those accustomed to the use of eye-pieces of high power; but every part of it is brilliantly illuminated, and difficult test-objects are exhibited by it with a sharpness and definition which we have seldom seen equalled. For objects which require to have a large surface in view at once, such a microscope is inappropriate; but for the purpose of minute examination of those in which the parts may be studied independently, we regard it as the best substitute for the achromatic microscope; and we can strongly recommend it to those who are debarred by the price of the latter instrument from possessing themselves of it. In employing doublets or triplets of high power as objectives in such a microscope, care must of course be taken (as when they are used singly) to avoid injuring them by contact with the object. For the most difficult test-objects, a triplet of $\frac{1}{3}$th of an inch focus should be employed; and the powers should successively diminish down to a doublet of $\frac{1}{8}$th of an inch, which may be advantageously employed for opaque objects. It is necessary to state that the performance of this microscope will very much depend upon the attention paid to the *illumination* of the object; on this we shall hereafter treat in detail.

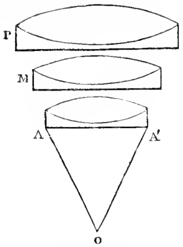
We shall next speak of eye-pieces which are intended to increase the size of the field in the most advantageous manner, without regard to the perfection of minute details. This object is ordinarily attempted by the substitution of two plano-convex lenses, or double-convex lenses of low curvature, for the single lens of the eye-glass. It has been proposed to make the same change in the field-glass; but, in our opinion, the loss by reflexion from two additional surfaces is by no means compensated by the diminution of aberration. We are ourselves, however, in the habit of employing an eye-piece, which we regard as greatly superior to that in ordinary use. It consists of a meniscus having the concave side next the eye, and a convex lens having the form of least aberration, with its flattest side next the object, nearly resembling, therefore, Herschel's aplanatic doublet. The field-glass is a double-convex lens of the form of least aberration. With this eye-piece we are enabled to obtain a field of 14 inches diameter (measured at the usual distance—10 inches) equally distinct and well illuminated over every part, and admirably adapted for the display of sections of wood, wings of insects, and objects of a similar description, and also for opaque objects. When employing it for these purposes, we much prefer the use of ordinary double-convex objectives to achromatic lenses; for the latter, being adjusted for a much smaller field, produce an image which is only distinct in the centre; and the former, being of low power, may have an aperture quite sufficient to admit the requisite amount of light. Even with deeper objectives, the performance of this eye-piece approaches much more closely to the effect of an achromatic microscope, than would be supposed by those who have only seen the ordinary one; and, when made on a small scale, it may be advantageously substituted for Mr. Holland's for all but the most difficult objects. The two additional surfaces are of course disadvantageous, by reflecting some of the fainter rays proceeding from the more delicate markings; but the increased magnifying power is gained with so little aberration, that a considerable general advantage is hence derived. We can regard no microscope as complete, without an eye-piece of this kind, with a set of ordinary objectives of low powers; for it will certainly do what no other combination with which we are acquainted can effect. The great improvements recently made in the construction of achromatic objectives, and the unquestionable fact that, for exhibiting the minute details of objects, they are infinitely superior to all other kinds, have had, we think, a tendency to blind microscopists to the advantages afforded by other combinations, where it is desired to obtain a view of the general arrangement of the parts of a large object, rather than to investigate its minutiæ.

We should recommend, therefore, that every achromatic microscope should be fitted with at least two Huyghenian eye-pieces, adapted expressly to the achromatic objectives; and that it should also have a meniscus eye-piece, with a set of ordinary object-glasses of long focus. And the best substitute for such a microscope, at least for the purposes of anatomical or physiological research, we believe will be found in Mr. Holland's doublet microscope, which should be furnished with his eye-piece for doublets already described, and with a meniscus eye-piece and ordinary object-glasses of low power. In this last form of compound microscope, there is the further advantage, that the high magnifying power of the doublets and triplets employed as objectives renders them available as simple microscopes; and this cannot be said of achromatic object-glasses, which have not yet been usually made of shorter focus than one-tenth of an inch, and which are not, therefore, of much use in themselves. No one, however, can be regarded as entitled to form positive conclusions in regard to difficult questions of microscopic enquiry, until he has availed himself of the very best means of observation at his command; and these are certainly to be found only in achromatic microscopes of the highest class.

For viewing large opaque objects, achromatic objectives of low power are often very useful, on account of the large quantity of light they admit, which supersedes the necessity of artificial illumination; this is a particular advantage in anatomical investigations, in which it is often especially necessary to avoid the reflection of condensed light from the surface of the object, on account of the confusion which is thereby occasioned.

The achromatic objectives at present usually made on the continent consist of *sets* of three or more, of which one, two, or three may be used at once. In this manner considerable variety of power may be gained; but the highest degree of perfection in the performance must be sacrificed to obtain it, since no *single* objective consisting of two lenses only can be thoroughly corrected, and each combination ought to be corrected for itself alone. The best achromatics made by British artists consist of combinations of two or three compound lenses, which cannot be separated; and thus

Fig. 165.



Section of the English achromatic combination.

every required power must be furnished by a distinct combination. The expense of a microscope fitted with the requisite number of these, however, is a great bar to its general employment. Other combinations have been constructed, therefore, in which the lens next the object may be removed, so as to diminish the magnifying power considerably; and the corrections are so adjusted as to be nearly the same when the two or when three compound lenses are used together. The difference between the performance of the best of these, and that of those most perfectly adjusted, is not, for general purposes, of much importance. Two sets of these separating lenses,—a high and a low one,—giving four powers, therefore, which may range from an inch and a half to one-eighth of an inch focus, will adapt the microscope, with the eye-pieces we have mentioned, to a great variety of purposes.

The power may be further varied by lengthening the body of the microscope, by drawing out the eye-piece, which should always be made capable of this kind of movement. This operates by increasing the distance from the object-glass of the image formed by it, and therefore augmenting the size of the image; the object must of course be brought somewhat nearer on the other side. We have already stated that the length of the body cannot be *much* increased with advantage; but a moderate variation will be found useful in many ways. It enables the magnifying power to be adjusted to almost any point intermediate between those given by the different objectives. Thus, one may give a power of 80 diameters, and another a power of 120; by using the first, and drawing out the eye-piece, the power may be increased to 100. Again, it is often very useful to make the object fill up the whole, or nearly the whole, of the field of view. This is especially the case, when it is itself not very transparent, and requires a strong light to render its details visible; in which condition a glare entering around its edges would very much interfere with its distinctness. When opaque objects, also, are being viewed by condensed light, in the modes hereafter to be stated, it is often extremely desirable to make them, or the discs on which they are mounted, fill up the whole field. In either case the drawing out of the eye-piece until the end is accomplished answers the object most simply and effectually. In the use of the micrometric eye-piece, also, which will be presently described, the capability of adjusting the magnifying power to a certain definite amount will be found of very great utility. It is to be borne in mind, however, that for giving the *highest* effect to the achromatic objectives, a certain fixed distance of the eye-piece is necessary; this is usually adjusted by the maker; but it may be easily determined by trial, since at any other the want of correction of the chromatic aberration will make itself apparent (however slightly) by the presence of coloured fringes around the images.

The degree of perfection in the construction of the optical part of a microscope, whether simple or compound, is judged of by the distinctness and comfort (by which we mean the freedom from strain or effort on the part of the observer) with which it exhibits certain objects, the details of which can only be made visible by combinations of lenses of high magnifying power and a near approach to correctness. Such are called test objects. They are of various degrees of difficulty. For testing the *penetrating* powers of a microscope, the lined scales on the wings and bodies of certain insects are commonly employed. The scales from the wings of many Lepidoptera are so coarsely marked, that a good ordinary compound microscope, or deep single lens, will make the lines apparent. But there are many others, which, under such magnifying powers, only show a flat unmarked surface, requiring lenses of large angular aperture to make their lines visible. One of the most beautiful of these, and at the same time most easily resolved, is the scale of the *Menelaus* butterfly; its longitudinal *striæ* may be seen in the best ordinary microscope, but they require a corrected object-glass to be well made out; and its transverse markings are only to be seen distinctly with a superior instrument. A scale with more delicate lines than these is the larger of those of the *Lycæna Argus;* the smaller one will be presently noticed. The most difficult of the test-scales, however, is that of the *Podura plumbea*, or common spring-tail; and a microscope which will distinctly exhibit its markings may be regarded as, for this class of objects, of the highest order. For *defining* power, however, another class of objects is needed. Among these one of the best is the small scale of the *Lycæna Argus* (or battledore), which, with an inferior instrument, appears covered with coarse longitudinal lines; but these, when more perfectly defined, are found to be resolvable into separate circular or oval dots, arranged in a linear manner. The curious hair of the Dermestes, and that of the Bat, require a microscope of good defining power to represent their forms with clearness and accuracy. We have ourselves been accustomed to employ the branching hairs of the common bee as tests of the correctness of a microscope of moderate power; for they have a remarkable tendency to produce fringes of colour, under most of the ordinary modes of illumination, unless there is a perfect freedom from chromatic aberration. The spiral fibres lining the tracheæ of many insects, also, will be found good tests of the defining power, and freedom from aberration, of a microscope. For still lower powers, we consider the glandular dots in the woody fibre of the resinous trees (especially those of the order Coniferæ) as very advantageous tests. They ought to be rendered distinctly visible with an object-glass of half an inch focus; and the depression in the centre should be clearly made out, with a perfect freedom from colour. We have seen objectives of English construction (in which a large aperture for showing opaque objects was the chief point aimed at) so defective in this respect, as to be far inferior in their exhibition of these and similar objects to French acromatics of much smaller aperture. We may here repeat the general rule, that those microscopes are, *ceteris paribus*, the best, which will show the most with the lowest magnifying power. It will sometimes happen that, although the details of an object may be made out with tolerable clearness, there is a sort of thin fog or mist over the whole field. This fault may proceed from the too great enlargement of the aperture of the objective, or from a faulty mode of illumination; or it may result from the imperfect extinction of the rays reflected within the body of the microscope from the surfaces of the lenses of the eye-piece, and from the interior of the tube itself,*—a fault which may be obviated by carefully coating the inner surface with a black covering, adapted to absorb all the false light. Black velvet may be advantageously used for this purpose. If the aperture be too great, the fault may generally be corrected by the use of *stops* beneath the stage, by which it may be diminished as required. This plan, which will be presently described more in detail, will be found very much to increase the applicability of low-power achromatic lenses of that large aperture which is desirable for opaque objects.

II. Of the mechanical arrangements of microscopes.

Having now described, with as much detail as the nature of this article permits, the principles on which the operation of the microscope depends, we shall next proceed to consider the means of arranging the optical portion of the instrument, so as to confer upon it the best and most varied application, keeping especially in view, however, the wants of the anatomist and physiologist. We shall begin by stating what, in any form of microscope, we regard as the essential conditions to be attained in its construction.

1. Steadiness and firmness in all its parts,

* [Or it arises, as suggested to the Editor by Mr. Powell, the eminent optician, from imperfection in the correction of the objectives.—Ed.]

so that it may be free from vibration. An amount of vibration, which is imperceptible when low powers are used, is sufficient to render the most perfect optical arrangements for high magnifying powers next to useless. That the whole instrument should be secured as much as possible from vibration, by being placed upon a steady table, and this on a steady floor, is of the first importance for its advantageous employment. But, as an entire freedom from this cause of vibration can rarely be obtained in an ordinarily-constructed house, the next point to be aimed at is such an arrangement of the optical portion of the instrument in regard to the object, that any vibration which takes place may affect both alike, in which case it will be scarcely perceptible. In many microscopes of ordinary construction the stage is comparatively motionless, whilst the body (containing all the optical portion) is subject to tremor; and in such instruments, when a high magnifying power is employed, the object is seen to oscillate so rapidly upon the slightest cause of vibration (such as a person walking across the room or a carriage rolling by in the street) that it is frequently almost indistinguishable. Various modes have been devised for obviating this inconvenience, the chief of which we shall hereafter notice.

2. Capability of accurate adjustment to every variety of focal distance, without movement of the object. It is now a principle almost universally recognised in the construction of good microscopes, that the stage on which the object is placed should be a fixture; and that the movement by which the focus is to be adjusted should be effected in the body or optical portion. Several reasons concur to establish this principle, which was, we believe, first insisted upon by Dr. Goring.* Among the most important we consider to be that, if the stage is made the moveable part, the adjustment of the illuminating apparatus must be made afresh for every change of magnifying power, whilst, if the stage is a fixture, the illumination having been once well adapted, the object may be examined under a great variety of magnifying powers, without its being changed in any respect. Moreover, if the stage is the moveable part, it can never have that firmness given to it, which it ought for many purposes to possess. It is almost impossible to make a moveable stage free from some degree of *spring;* so that, when the hands bear upon it in adjusting the position of an object, it yields to an amount which, however trifling, becomes apparent with high powers by the alteration of the focus. We might add many more reasons, but these will here suffice. It having been determined, then, that focal adjustment should take place in the optical portion of the microscope, the next point for consideration is the mode of effecting it. This should be such as to allow free range from a minute fraction of an inch to three or four inches, with equal power of obtaining a delicate adjustment at any part. It should also be so accurate that the axis of the instrument should not be in the least altered by movement in a vertical direction; so that, if an object be brought into the centre of the field with a low power, and a higher power be then substituted, it should be found in the centre of *its* field, notwithstanding the great alteration in the focus. In this way much time may often be saved by employing a low power as a *finder* for an object to be examined by a higher one; and, when an object is being viewed by a succession of powers, no readjustment of its place on the stage is required, such as would otherwise be necessary for each. The best modes of securing these ends, also, will be considered in their proper place.

3. The power of placing the instrument in either a vertical or a horizontal position, or at any angle with the horizon, without deranging the adjustment of its parts to each other, and without placing the eye-piece in such a position as to be inconvenient to the observer. It is certainly a matter of surprise that opticians should have so long neglected the very simple means which are at present so commonly employed, of giving an inclined position to microscopes; since it is now universally acknowledged that the vertical position is, of all that can be adopted, *the very worst.* We do not ourselves consider the *horizontal* position of the body and its appendages at all an advantageous one, although it has been adopted in some of M. Chevalier's latest and best instruments. In the first place it requires that the whole microscope should be raised so much above the level of an ordinary table, as to bring the eye-piece to the height of the eye of the observer when sitting upright at his ease; if this be not done, a constrained and consequently disadvantageous position of the head is required on his part; and if it be, all the manipulations must be executed at an elevation very inconvenient and fatiguing to the arms. Moreover either the stage must be rendered vertical, in which case all the objects must be so secured (to prevent their slipping) as to render the necessary movement of them very difficult; or, the stage being horizontal, the direction of the rays must be changed, after they have passed through the object-glass, by a prism or a mirror placed at an angle of 45° in their course, as in M. Chevalier's construction, which we think a decided disadvantage, as introducing another source of imperfection and error. We believe that it will be generally acknowledged, that an inclination of about 45° to the horizon is the most convenient for unconstrained observation; and the instrument should be so arranged, that, at such an inclination, the stage may be so far elevated above the table, that, when the hands are employed at it, the elbows may rest upon the table. In this manner a degree of support is attained, which gives such free play to the muscles of the hands, that movements of the greatest nicety may be executed by them; and the

* See Pritchard and Goring's Microscopic Illustrations.

fatigue of long-continued observation is greatly diminished. Such minutiæ may appear too trivial to deserve mention; but no practised microscopist will be slow to acknowledge their value. At the inclination we have mentioned, the departure of the stage from the horizontal position will not be such as to render it necessary to confine the objects with more than a slight force, and accordingly they may be moved by the hands with considerable freedom; and light objects may be placed upon a slip of glass without any confinement, or covered with talc if necessary, and yet be in little danger of falling off it. These are conveniences which are of more value in practice than they may appear in theory; for it will often be found that the saving of a little time in the adjustment of the microscope is of great importance in the observation of objects which are undergoing change. There are some objects, however, which can only be seen in a vertical microscope, as they require to be viewed in a position nearly or entirely horizontal; such are dissections in water, saline solutions undergoing chrystallisation, &c. For other purposes, again, the microscope should be placed horizontally, as when the camera lucida is used for drawing or measuring. It ought, therefore, to be made capable of every such variety of position.

4. The last principle on which we shall here dwell is *simplicity* in the construction and adjustment of every part. Many ingenious mechanical devices have been invented and executed, for the purpose of overcoming difficulties which we cannot but regard as trivial. If all these were combined in one instrument, a degree of complexity would be thereby engendered, which would prevent it from being generally available. Our own experience leads us to the conclusion, that a moderate amount of dexterity in the use of the hands is sufficient to render most of these superfluous; and without such dexterity, no one, even with the most complete mechanical facilities, will ever become a good microscopist. We shall hereafter describe, however, some of those which are in most general use; premising that we cannot speak from much experience of their applicability, since we have ourselves found no difficulty in doing without them, as we recommend our readers to do. Although a large box, well filled with glittering brass implements of various shapes and sizes, may have a very inviting appearance, it will often be found that these are more for show than use, and add to the expense of the instrument in a proportion far exceeding their utility. Among the conveniences of simplicity, the practised microscopist will not fail to recognize the saving of time effected by being able quickly to set up and put away his instrument. Where a number of parts are to be screwed together before it can be brought into use, interesting objects as well as time are not unfrequently lost; and the same cause will often occasion the instrument to be left exposed to the air and dust, to its great detriment, because *time* is required to put it away. With those who are not practised in mechanical manipulation, this is especially necessary; indeed we have often known a slight advantage on the side of simplicity of arrangement cause an inferior instrument to be preferred to a superior one. Yet there is, of course, a limit to this simplification; and it ought never to interfere with due attention to the principles already specified.

Before proceeding to notice any of the ordinary forms of *stands* for simple or compound microscopes, we shall make a few remarks on the best means of carrying on a dissection under a magnifying power. The simplest of all means of effecting this, where the object is large and opaque, and a low magnifying power only is requisite, is to fasten it down upon a board, to any part of the edge of which may be affixed, by means of a small clamp, a jointed stem, carrying a socket or cell, into which a lens mounted in the usual manner may be dropped. This stem, being capable of movement in every possible direction, but having also sufficient stiffness in its joints to remain in any position in which it may be placed, appears to us preferable to any other plan of supporting the lens. The object may be illuminated, if necessary, by light condensed through a convex lens, or reflected from a concave mirror. If the dissection must be carried on under fluid, the only variation necessary is the use of a shallow trough, instead of a board, which may be filled with water, dilute spirit, or oil of turpentine, as the case requires; to the edge of this trough the clamp may be fixed in the most convenient position; and the bottom of it (if of metal) may be covered with a piece of cork, or a layer of resin and bees-wax, for the purpose of receiving the pins necessary to fix the object. Where the object is smaller, and the dissection may be carried on under a higher magnifying power, we can strongly recommend the use of Mr. Slack's dissecting microscope, of which a description and figures may be found in the 49th volume of the Transactions of the Society of Arts.*

Dissecting instruments.—The instruments employed in microscopic dissection must of course vary with the nature and size of the object. The following will, we think, be found most generally useful. Small pointed scalpels. The iris-knife is a convenient size and form for many purposes. Scarpa's curved cataract needle is an instrument which we have found extremely serviceable. Fine scissors, one leg of which should be fixed in a long handle, and the other kept apart from it by a spring, so as to close by the pressure of the finger and to open of itself; the blades should both be pointed and sharpened on a hone; these will

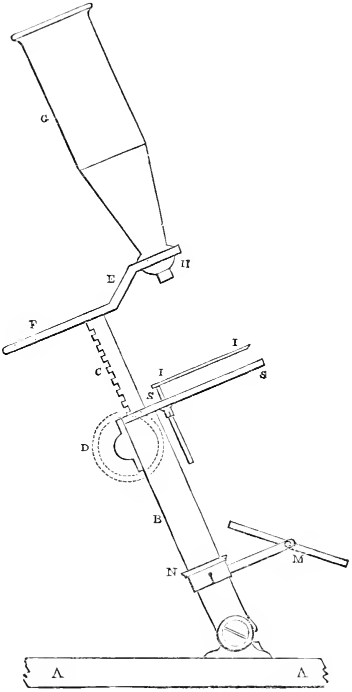
* [Mr. Powell, the optician, Clarendon-street, Somers' Town, has enlarged and improved considerably Slack's dissecting microscope; and Mr. Ross, of Regent-street, has also on sale a convenient form of dissecting microscope, which is delineated in the Penny Cyclopædia, art. 'Microscope.'—Ed.]

be found much superior to any form of knives for cutting *through* delicate tissues without disturbing them. Swammerdam is said to have made great use of such implements, in his dissections of insect structures, which, from the accounts of them on record, seem almost to have surpassed any which have been since executed. The curved forceps recommended by Mr. Slack, we also have used with much advantage. For more minute dissection we can strongly recommend *common needles*, and cutting implements which may be easily manufactured from them, by grinding down their sides upon a hone. These may either be fixed in wooden handles, or, which is much better, held in little instruments resembling crayon-holders, specially constructed for their reception. The dissector is thus enabled to give to his needle the effect of a long elastic point or of a short stiff one, by simply altering the part at which it is held. In the ivory handles of these holders, also, there is a receptacle for the needles, which makes the whole of this useful little apparatus complete in itself.*

Many microscopists, especially on the continent, are in the habit of making great use of the *compressorium*, an instrument in which an object may be submitted to graduated pressure between two plates of glass, the parallelism of which is perfectly maintained. The results obtained by such compression, however, must be accepted with great caution, and need to be corrected by those views of the object which are gained without that distortion of it to which it is liable in this method. The class of investigations in which the compressorium is most valuable, is that in which such structures as the minute ovum need to be closely scrutinized, without any further change in their shape than may render their contents more distinctly visible. For such purposes we believe that a steady hand and a well-made aquatic box will answer the purpose sufficiently; but to those who prefer relying on mechanical assistance, the compressorium will be a useful instrument.

We shall now proceed to describe some of the modes of mounting and arranging simple and compound microscopes, which appear to us most convenient. The first that we shall notice is a form which has cheapness and simplicity to recommend it, and which, if well made, is capable of an adjustment sufficiently delicate for all ordinary purposes. It is a slight modification of one of Mr. Pritchard's.† *A (fig.* 166) is the stand, or basis, into which the pillar is screwed. This may be variously constructed, according to the purpose for which it is designed. If *bulk* be an object, it may be a round disk of lead; but if *weight* must be avoided, a thick tablet of mahogany about six inches square, or five inches by seven, (the longest side being in the direction of the movement of the pillar,) is preferable. If great

Fig. 166.



Elevation of ordinary compound or simple microscope.

A, base; B, hollow pillar, with joint at bottom; C, triangular rack; D, nut by which it is moved; E, bar carrying compound body; F, other end adapted for simple magnifiers; G, compound body; H, objective; I, spring fork; M, mirror attached to sliding tube, tightened by the nut, N; S, stage.

portability be desired, the pillar may be made to screw into the top of the box that holds the apparatus; but this plan should not be adopted, unless all the smaller fittings be contained in a tray which may be lifted out, in order that there may be no necessity for opening the box when the instrument is in use. The pillar is a thick tube of brass about six inches long, with a large screw at the bottom for being attached to the stand, and a joint above this, for allowing it to be inclined at any angle. If this joint be well constructed, the instrument will remain in any position in which it is placed, without any steadying rod or perceptible vibration. Within the tube is a triangular bar, with a rack cut on its posterior edge; this may be raised or depressed from the top of the tube, by turning the milled head, which carries a pinion working into the rack. Particular attention

* Such needle-holders are sold by Mr. Pritchard, Fleet-street, London.

† Microscopic Illustrations, 2nd ed. p. 82.

should be paid to the action of this rack; it should work through a triangular socket at the top of the pillar of at least an inch long, closely embracing the bar, so that it may be moved up and down without the least shake, or variation from its axis, or tendency to slip, when loaded with the full weight it has to carry; at the same time, it should be sufficiently *sensitive* to be moved by the slightest rotation of the pinion, which may be effected, not only by the milled head, but by a lever, as in Mr. Holland's microscope. Such a rack will afford the means of focal adjustment for doublets and triplets of high power, as well as for ordinary magnifiers. If it be considered desirable to vary the length of the pillar, and consequently the height of the stage, this may be effected by attaching the rack, stage, &c., to a piece of tube which shall slide within the one that is attached to the base; if the top of the lower one is *sprung*, and surrounded by a clamping screw, the upper one may be firmly fixed at any elevation. This plan has been proposed by Dr. Goring for the pillar of his engiscope; but we consider it perfectly inapplicable to a large instrument, of which the pillar should be solid, in order to avoid oscillation. The triangular bar carries at its top a double arm, attached to it with a screw and a small milled head, by which its movements may be rendered more or less free. This arm should be thick and well hammered, in order that, when it carries the compound body, it may not be subject to vibration. The object of the double bend in one side of it is to allow the *nose* of the body, which is screwed into the hole on that side, to project below it, so that the magnifiers may be attached on its under side; by this means, the necessity for unscrewing the body every time that the magnifier is to be changed (which is requisite where the magnifier is screwed into the arm and the body into it) is avoided, without any increase in the length of the rack, which would otherwise be necessary for low powers. The other side of the arm carries the magnifiers, when employed as single lenses; the same set may be used as are fitted to the compound body, their interior being *screwed* for attachment to it, and their exterior being adapted to drop loosely into the hole of the second arm. For such a microscope, we should recommend a series of ordinary lenses from $2\frac{1}{2}$ or 2 inches focus to $\frac{1}{8}$th of an inch, and two or three doublets from $\frac{1}{10}$th to $\frac{1}{20}$th, with a triplet of $\frac{1}{30}$th. These may all be used as objectives with a meniscus eye-piece; though, for the latter, Mr. Holland's will, in most cases, be preferable. The stage of this microscope may be a simple plate, attached to the top of the pillar, as in *fig.* 166, with a spring stage and other appurtenances adapted to it. We are inclined to recommend for such a microscope, however, for the sake of simplicity and facility of use, a stage in which the ordinary principle of fixity is in some degree departed from. The upper part of it consists of a thick and strong fork, projecting about 2 inches and about $1\frac{1}{2}$ inch broad, of well-hammered brass, firmly attached to the top of the pillar; at about $\frac{3}{4}$ths of an inch below this is a plate of similar dimensions, with an aperture of about an inch. Bearing upon this lower plate by a spiral spring, and guided by vertical pins working through apertures in it, is a thin moveable plate, which is constantly being pressed upwards by the spring against the fork. This stage combines, in a degree which renders it an extremely convenient one, the advantages of the ordinary spring-stage, and the fork. The objects, whether placed in sliders, on slips of glass, or in aquatic boxes, are readily slid under the prongs of the fork (which should be bevelled off on the under side so as to allow them to enter), and are held by the spring with sufficient firmness in any position, whilst ready movement is also permitted them. The fork may have a vertical hole drilled in it on each side, for holding the stage forceps or other such instrument; and it may be made thick enough to allow of a lateral hole for fixing the condenser, without being too much weakened. The thickness of the fork will be of no kind of inconvenience, as the nose of the microscope will have free play from side to side between its prongs. To the lower plate may be attached ground-glass, stops, condensers, polarising apparatus, or any other required fittings. The disadvantage of this stage is that it affords no firm support to the object, which is in some instances of importance. This may be obtained by simply adapting a plate to the upper side of the fork, which may be received into grooves on its lower surface; and this plate may then be considered as the stage. Whenever such an instrument is being adapted to the purpose of dissection, all that is necessary is to raise up a support for the hands on each side of the stage, which may consist of books, or still better of blocks of wood cut to the form of the outside of Mr. Holland's case; and the height of the stage being then adjustible by the sliding tube of the pillar, all the advantage of Mr. Holland's microscope, except its *self-containedness*, may be secured. We have only further to mention the mirror, which should be at least two inches in diameter, and have one of its sides plane, and the other concave. Its stem should be attached to a short piece of *sprung* tube sliding over the pillar, and capable of being secured in any situation by a clamping screw.

If a still more portable microscope be required, combining considerable range of power with great exactness of adjustment, we can strongly recommend an instrument constructed upon the plan of the large one subsequently to be described, (*fig.* 167,) but upon about two-fifths of the scale. Its pillar may either be screwed into the lid of the box containing the apparatus, or mounted on a tripod similar to that which is used for portable telescopes,—the tripod being reversed, and the legs being folded round the stem, when it is packed in its box. The delicate focal adjustment of which this microscope is susceptible renders it more advantageous than the one last described, when deep magnifying powers are being employed;

and its portability is a great recommendation. The one in our own possession is packed, with its tripod, into a box whose outside dimensions are $7\frac{1}{2}$ inches by 5, and its depth only 2, and this also contains a short body with meniscus eye-piece, four ordinary magnifiers, and three doublets and triplets, which may be used singly or as objectives, illuminating lenses and speculum, aquatic boxes, and other small apparatus,—the weight of the whole being no more than $2\frac{1}{2}$ lbs, although a magnifying power of 450 diameters, with sufficient penetration to exhibit the markings on the Podura, and with perfect steadiness, may easily be obtained by it.

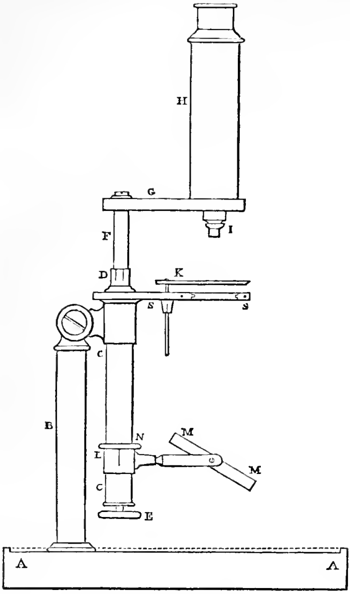
The instruments we shall now describe are not adapted for use in any other way than as compound microscopes. Their size and weight are such as would render them far less convenient than the smaller forms already described for use with simple lenses, although there is no other reason why they should not be thus employed. Every constructor of microscopes has his own favourite model; and there are few recently made instruments of the highest class which do not possess some particular recommendations. Amidst the numerous claimants to our notice, we shall select two; of which the first is the form adopted by one of the best constructors of achromatic objectives in this country; and the second is the one which we have ourselves had in use for several years, and which we do not desire to lay aside for any we have seen. With respect to the former, our limited space compels us to refer to the article Microscope in the Penny Cyclopædia, where a delineation and full description of Mr. Ross's Microscope will be found.*

We shall now describe the microscope which we have ourselves been accustomed to employ, and state what we regard as its advantages; not omitting to notice the objections which may be brought against it, and bearing in mind that every microscopist is naturally most partial to the form which he has himself adapted to his own ideas of convenience. It is principally constructed according to the plans of Mr. Pritchard and Dr. Goring; and we may observe *in limine*, that the objections which have been brought against any form of construction in which the body is screwed by its lower extremity to a horizontal arm, as placing it in the most unfavourable position for vibration, independently of the stage, are applicable only to instruments which are not made with sufficient solidity; for, having had an opportunity of comparing the quality in this respect, of Mr. Ross's microscope, with our own, the two being placed in exactly the same circumstances, we could not find that there was any inferiority on the part of the latter. It must be borne in mind, that every increase in the size and power of a microscope must be accompanied by *more than* a corresponding increase in solidity, in order to guard effectually against oscillation.

The stand or basement is a slab of solid mahogany 12 inches square and $1\frac{1}{4}$ inch thick, loaded with lead at the corners, and having a strip of thick baize, about $1\frac{1}{2}$ inch broad, glued round the edge of the under side; the whole weight bears upon the baize, which does not readily communicate vibrations; and the large surface over which the pressure is distributed gives the instrument a degree of *imperturbability* which would scarcely have been anticipated. The slab is surrounded by a slightly elevated rim; and it thus serves as a most convenient little table, on which the various pieces of apparatus required for microscopical observation may be carried about with the instrument without any danger. The pillar of the microscope carries at its lower extremity a screw, above which is a flange or shoulder of 2 inches diameter; the screw is received into a socket let into the wooden foot, and firmly attached to it, and itself having a shoulder of equal size; so that, when the pillar is firmly screwed down upon it, there is not the least tendency to vibration between the two. The socket is not let into the middle of the base, however; but its centre is only $2\frac{1}{2}$ inches from one of the sides, and $9\frac{1}{2}$, therefore, from the other; so that, in fact, when the microscope is placed vertically, the centre of the stage pretty nearly corresponds with the centre of the foot. The object of this is to give a decided preponderance in weight to the front of the foot in all positions of the microscope; for we are inclined to think that much of the oscillation so frequently complained of in microscopes is to be

* [Without wishing in the least degree to detract from the merit of Mr. Ross's microscope, (to which, on the contrary, he bears willing testimony,) the Editor deems it but justice to refer to a very beautiful instrument constructed by Mr. Powell, which he has employed for some time, and which is also used by several observers in this city. The body of the microscope moves on a triangular bar, having a bearing of three inches, which renders it very steady. The coarse adjustment is obtained by a rack and pinion, attached to which are *two* large milled heads, which allow of the body being adjusted with either hand. The fine adjustment has also two milled heads, only two inches apart from the coarse one, and their axis being horizontal and parallel to each other, renders the motion of the hand from one to the other perfectly easy, without removing the eye from the body of the microscope. The stage is seven inches square. The convenience of its being thus large is, that the hands do not interfere with the object when adjusting it. The heads that move the stage have their axis in the same line, and so placed that with the same hand the stage may be moved in all directions; this is convenient when viewing an object, the surface of which is very irregular; with the right hand you can move the stage, and there being two heads to the adjustments for the body, with the left the object can be adjusted into focus. There are likewise two milled heads to one motion of the stage, by which means both hands may be employed at the same time, which is sometimes requisite. On the same bar that the body rests, moves the "achromatic condenser," by which arrangement it is certain to move in the same line with the body, which is most essential, for unless it did so when using different power object-glasses, the axis of the lenses would not coincide. There are many other conveniences and improvements to this microscope which cannot be mentioned in this brief notice.—Ed.]

Fig. 167.



Superior Compound Microscope.

A A, base; B, pillar with joint at the top; C C, stem, containing square tube D, which is moved by a fine screw turned by the nut E; within this tube slides the square bar F, carrying the arm G; into this is screwed the tube H, within which the compound body slides; I, the objective; K, stage-fork; L, sprung tube, tightened by the nut N, carrying the frame of the mirror M.

attributed to the fact, that, when the instrument is much inclined, the hinder foot receives nearly the whole weight, and the portions of the instrument on the two sides so nearly counterpoise each other, that a very slight cause will communicate an oscillation to the whole. We can strongly recommend to our readers a basis of this kind, having not only our own experience of its benefit to guide us, but that of friends whom we have induced to adopt it, and whose previously unsteady microscopes have been greatly improved thereby. It certainly does *not* possess the merit of portability; but this, in a large microscope for observations of the highest kind, ought not to be a consideration. Nothing is easier than to have a separate tripod of the ordinary kind for use when occasion requires. To such a tripod Mr. Ross* has recently applied a method of construction, which he states to be very effectual in obviating vibration; but we cannot speak from experience in regard to its use; and being well satisfied with our own much simpler and less expensive plan, we do not see the necessity for it.

The pillar is just an inch in diameter, and consists of a stout brass tube loaded with lead. On the firmness of this part much depends. It is 8 inches from the foot to the centre of the joint. The middle piece of the joint is $\frac{1}{5}$th of an inch thick; and to this is attached a tubular clamp with a binding screw, which closely embraces the stem. This mode of construction we adopted in accordance with the recommendation of Dr. Goring and Mr. Pritchard;* but we are doubtful if its advantages counterbalance the disadvantage of a certain want of fixity which it imparts to the remainder of the instrument supported by it. The stem is a thick brass tube of about $\frac{9}{10}$ths of an inch in diameter; to the upper part of it is firmly attached the stage, which is composed of a simple plate of well-hammered brass, $\frac{1}{4}$ of an inch thick; its length from the front of the pillar is 4 inches, its breadth $2\frac{1}{2}$ inches, and the diameter of its aperture $1\frac{1}{2}$ inch. The only fitting constantly attached to it is the fork, of which the two wires work through sockets projecting from the under side of the stage. This fork is made sufficiently thin to possess a certain degree of elasticity; and, being firmly held in any position by the friction of its wires, it is a very useful means of holding aquatic boxes, slips of glass, large sliders, &c., affording, by its wide opening, (2 inches,) considerable freedom of movement to the object. The utility of this fork will depend upon the goodness of its construction in the first instance; it ought to work easily, and yet hold tightly in any position. The sockets through which its wires pass should be *sprung*, so that they may be tightened at pleasure, should they work loose. The stage has a slight rim projecting into the lower side of the aperture, in order to hold various fittings which are attached to it by a bayonet catch, and holes are drilled in various parts of the stage (the massiveness of which prevents its being weakened thereby) for the reception of the pins of the forceps, condenser, &c. The stem carries a sprung tube, to which the mirror is attached, in the manner to be presently noticed.

From the top of the stem projects a square tube, a little more than $\frac{6}{10}$ths of an inch each way, the upper end of which is sprung, so as to grasp with sufficient firmness a solid bar of half an inch square, which slides up and down within it. The upper end of this bar carries the arm to which the body of the microscope is attached; on the accuracy of its formation the *truth* of its movement will of course depend; but if well made, a rise and fall of $3\frac{1}{2}$ inches may be allowed to it, without the slightest alteration in the position of the axis of the body which it carries. The advantages of this sliding movement over the rack commonly employed for the coarse adjustment we regard as considerable; very much time is saved; for the arm may be shifted from its greatest to its least distance from the stage, in scarcely more time than is

* Microscopic Journal, No. 2.

* Op. cit.

required for making the slightest adjustment. The axis of the body is never changed in the least degree,—which we have rarely found in rack adjustments, owing to the pressure of the pinion against one side of the bar; and thus an object is always kept in the centre of the field, whatever change made be made in its focal distance by an alteration of the magnifiers. By a little practice, the power of making adjustments of extreme minuteness may be obtained, if the bar have been originally filed so true that it works with perfect smoothness in every part. An additional adjustment, which may be made of any required fineness, is provided for, however, by making the square tube or socket itself moveable, and connecting it with a micrometer screw worked by a large milled-head at the bottom of the stem. By turning this screw, the socket, and the bar which it carries, are raised or depressed in any minute degree; and the socket being made to work through stuffing-boxes closely packed with cork, all twisting on its axis by the action of the screw is avoided. On the fineness of the screw the delicacy of the adjustment will of course depend. That which we have employed has forty turns to the inch; and the milled-head being $1\frac{1}{2}$ inch in diameter, or about $4\frac{1}{2}$ inches in circumference, a movement of one-fiftieth of its periphery, or something less than $\frac{1}{10}$th of an inch, will affect the arm to the amount of $\frac{1}{2000}$th of an inch. We should recommend, however, a screw rather finer than this. By dividing a circle on the milled head, and affixing an index-point to the bottom of the stem, the amount of motion given may be known to a great nicety, and thus the thickness of a minute object laid upon any surface may be measured. If its upper side be brought exactly into focus, and it be then removed, and the surface on which it has lain be brought into focus by the micrometer screw alone, the number of divisions over which the index has passed will of course indicate the thickness. This method, which was proposed by Mr. Valentine,* answers very well for such objects as the vessels of plants, scales of insects, &c. which can be completely isolated, when a sufficiently high power is employed, so that distinctness can only be obtained at one point. We consider it a great advantage of this kind of adjustment, that it is effected at a considerable distance from the stage, and that the hand is therefore in no danger of deranging the position of objects or apparatus connected with it.

The arm which carries the body is attached to the top of the bar by a screw-pin passing through the former, by which it is enabled to traverse from side to side. This movement will often be found extremely useful, both in the examination of different parts of objects which it is desirable not to move, and in changing magnifiers, &c. on the body; the want of it we consider one of the chief inconveniences in Mr. Ross's form of construction. The arm is $\frac{3}{8}$ths of an inch thick, and broad enough at the part farthest from the centre to receive the body, which is not made tapering in the usual manner, but is attached by a screw of $1\frac{1}{2}$ inch diameter, with a large shoulder above it. By this mode of attachment, and by the massiveness of the arm itself, all vibration from the top of the bar is prevented; at least *we* have not been inconvenienced by it. When the bar is pushed into its socket, so that the arm approaches the stage, (as when high powers are used,) no oscillation can arise from *its* vibrations; and the socket itself works through an aperture in the stage-plate, to which it is so closely fitted that no oscillation can arise in that point; so that, both in theory and practice, we find the form here proposed unobjectionable on this score. It is true that, when the bar is drawn out to its full extent, oscillation *may* arise; but this is never the case, except when low powers are being employed, and then we altogether fail to perceive it. In the construction of the body there is nothing worthy of peculiar remark; and, as we have already described the various modes of magnifying the object, we shall therefore now pass on to consider the best means of illuminating it.

The perfect *illumination* of the object is a matter of the utmost importance, especially when high magnifying powers are being employed. There are many difficult objects which require to be viewed under a great variety of aspects, in order that their true characters may be determined; and there are not a few whose structure cannot be understood at all, even with the most perfect arrangement of the optical portion of the microscope, unless similar attention be bestowed on the concentration of the light by which they are viewed. We shall, therefore, bestow on this subject more attention than it has ordinarily received.

For transparent objects of large size, which are being viewed with low powers, such as sections of wood, wings of insects, &c. we find a concave mirror by far the most simple and, at the same time, effective means of illumination; and the optical errors to which it gives rise are not such as to interpose any practical difficulty in its use. It should be, for such a microscope as we have described, of greater size than that ordinarily employed; three inches may be regarded as a good diameter. It should be set, by an universal joint, upon a piece of tube fitted to slide stiffly up and down the stem which descends from the stage. In this manner its distance from the object may be readily varied; and the degree of concentration of light effected by it will thus be easily adapted to the character of the object to be viewed. Thus, if it be pushed near the stage, the pencil of convergent rays will not be nearly brought to a focus, and a large surface will be illuminated with a moderate light. But if it be drawn nearer the opposite end of its range, the rays will be more concentrated, so that a smaller surface will be illuminated, but with much greater brightness. By the former adaptation we are enabled to illuminate, with great equality, and by means of the ordinary lamp-flame, an area of three-eighths of an inch in diameter, with sufficient intensity to produce a very bright

* Trans. of Soc. of Arts.

field of fourteen inches. In viewing large objects for which great perfection is not required, we find it advantageous to interpose a ground-glass at about half or three quarters of an inch distance beneath them; this is easily adapted to the under side of the stage. It serves to produce an extremely equable diffusion of the light over a large field, and to deaden the glare which is occasioned by the direct admission of so large a quantity; but, if applied to objects which require to be seen with great distinctness, it will be found to produce a kind of fog which seriously impairs the power of the microscope; and with objects of any difficulty it is quite inadmissible. In viewing objects, however, of the largest size that the microscope can receive, by a good diffused daylight, the ground-glass is never required. A bright cloud, *opposite to* the sun, is then the best source of illumination. For the purpose of effecting these and other adjustments of the mirror, we have found it convenient to have the tube which carries it *sprung*, so as to slide rather loosely on the stem, and to secure it in any particular situation by means of a large milled head which screws on one end of the tube, and clamps it upon the stem.

The plane mirror, with a condensing lens between it and the stage, is preferred by many to a concave mirror; and for certain objects it is, without doubt, superior. For ordinary use, however, we prefer the concave mirror, for the following reasons:—Its effects are obtained by a single adjustment; whereas, in the use of the plane mirror and lens, two adjustments are required: and if (as we shall presently state to be often desirable) the mirror be thrown quite out of the axis of the optical part of the instrument, it is difficult to adjust the condenser with correctness. Further, in order to obtain light enough for a field such as we have mentioned, the condensing lens must be nearly three inches in diameter, and thus becomes very cumbrous and inconvenient. For objects of a high class the concave mirror should of course not be employed; but for these the common condenser is by no means adapted, and must be put aside for a superior one, such as we shall presently describe. The plane mirror and condenser enable the observer, however, to obtain an additional variety of illumination, which is often advantageous; and by a simple modification, proposed by Mr. Varley, the light of a bright cloud may be artificially imitated by them. The means of doing this consist in covering the surface of the plane mirror with carbonate of soda or pounded glass, by which the direct solar rays are reflected very much as by a white cloud. We have also seen a plaster of Paris mirror employed for the same purpose, and with good effect, where, on account of the transparency of the object, it was necessary to reduce the amount of light sent through it, without interposing any screen that should produce indistinctness.
